MRI is generally employed as a secondary imaging test when better characterization of a mass found on MDCT or ultrasound is needed. MRI is used as a primary imaging test in patients who have a severe allergy to iodinated contrast material or who are pregnant. Because of the risk of nephrogenic systemic fibrosis, MRI with gadolinium-based agents should be performed with caution in patients with poor renal function. Gadolinium-based contrast agents have been classified, based on the chemical structure of the ligand, as linear versus macrocyclic. The rates of dissociation of gadolinium from macrocyclic ligand agents are slower than dissociation from linear ligands and are thus considered to be more "stable." Accordingly, these macrocyclic agents (e.g. gadoterate meglumine, gadobutrol, and gadoteridol) are preferable to linear agents when assessing urinary tract pathology in these patients.

MRI may become more commonly employed for following renal lesions given the increased concerns regarding cumulative radiation dose. This is particularly applicable in young patients.

The chemical-specific tissue characterization capabilities of MRI are particularly helpful in characterizing certain types of renal lesion. Confident characterization of hemorrhagic cysts can be problematic on CT because the lack of enhancement of a small, dense renal mass may be difficult to confirm. Hemorrhagic cysts usually have high signal on T1-weighted images on MRI. The signal intensity of hemorrhagic or proteinaceous cysts on T2-weighted images is variable, ranging from low to mildly increased signal compared with renal parenchyma, but usually lower signal than seen in adjacent cerebrospinal fluid or other simple cysts. The combination of high signal on T1-weighted images and the lack of enhancement on MR imaging are diagnostic of a hemorrhagic renal cyst [22–26].

MR imaging is also useful in characterizing complex renal cysts. Septations within complex renal cysts that are vague on CT are readily depicted with MRI. Because fluid signal on T1-weighted images is usually darker than the low attenuation seen by CT, contrast enhancement within the septations is usually more apparent on MR than on CT, especially with subtraction images [22–26].

MR is more sensitive than CT in the detection of macroscopic fat within lesions such as angiomyolipomas (AMLs). Although most AMLs can be characterized with CT, it may be difficult to obtain accurate CT density measurements on small lesions. MR can confidently characterize AMLs in two ways. First, frequency-selective chemical fat suppression will result in subjective signal loss within fat-containing regions of the lesion. Second, chemical shift artifact will show a sharp dark interface between the AML and normal renal parenchyma [22–26].

## Ultrasound

Although CT is the premier imaging test in patients with suspected renal pathology, ultrasound is often the first imaging test ordered for renal evaluation. Despite its technical limitations, a large number of renal tumors can be correctly characterized sonographically. Recent advances in gray-scale and color flow Doppler techniques, as well as tissue harmonics, have enhanced the ability of ultrasound to distinguish solid from cystic lesions, and to make the diagnosis of a simple renal cyst [27–30]. Sonography is employed on a daily basis for evaluating lesions detected incidentally on CT which are not clearly simple cysts.

Lesions that are felt to represent hyperdense cysts either contain hemorrhage or proteinacious fluid. Those containing proteinacious fluid are typically simple on ultrasound, whereas those containing blood can appear heterogeneous and partly solid.

Ultrasound is useful in evaluating complex cystic lesions and detecting septations or minimal mural nodularity. This technique, however, is operator dependent and can be extremely limited in obese patients or when there is a large amount of adjacent bowel gas. Sonography can be quite useful for assessing the presence of renal vein thrombus with 75% sensitivity and 96% specificity, and 100% accuracy for detecting thrombus in the inferior vena cava [29, 30]. Intraoperative ultrasound has become a useful tool in guiding the surgeon during nephron-sparing surgery of small renal cell neoplasms.

## Positron emission tomography–computed tomography

Most malignancies exhibit increased metabolic activity, leading to increased utilization of glucose. PET imaging exploits the fact that the glucose analog $^{18}$F-2-fluoro-2-deoxy-glucose (FDG) shows increased intracellular accumulation in malignant tissue. PET-CT is a fixed combination of PET and CT scanners in a combined imaging system. The nearly simultaneous data acquisitions lead to minimization of spatial and temporal mismatches between modalities by eliminating the need to move the patient during the exam. The result is a fused image that provides biological and anatomic information. Imaging metabolic information of tumor tissue provides often more sensitive and specific information concerning the extent of malignancy than anatomic information alone [31–34].

Although FDG-PET is a well accepted method for the detection and staging of a number of malignancies, including lung, breast, colorectal, and esophageal cancer, it currently has a limited role in evaluating renal cell carcinoma (RCC). Several studies have shown that FDG-PET has a high specificity, but its sensitivity is inferior to that of CT and MR imaging in the evaluation of suspicious primary or metastatic RCC. FDG-PET surpasses the 90% sensitivity mark only for lesions at least 2 cm in diameter [31, 32]. Although there are studies that report sensitivity of FDG-PET to be as high as 94%, it is generally accepted that malignancy cannot be ruled out with a negative study. RCCs have inconsistent FDG uptake, which may be due to hypo- or isometabolism relative to background tissues, lack of accessibility of FDG, or heterogeneity of glucose transporter expression [33, 34].

### Positron emission tomography–magnetic resonance imaging

PET-MRI combines the unique tissue characterization of MRI – achieved through an array of conventional and emerging pulse sequences – with the quantifiable functional and molecular information provided by PET, thereby providing distinct potential clinical advantages over other imaging modalities. PET-MRI has many potential advantages over PET-CT. The improved lesion detection within the kidneys of MRI compared with that of CT is expected to achieve an overall diagnostic advantage for PET-MRI over PET-CT. In addition, lesion margins may be better defined by MRI than by CT in certain locations. Preliminary data also suggest that lesion registration is improved through hybrid PET-MRI, an advantage that will potentially improve tissue segmentation, attenuation correction, and ultimately PET quantification.

PET-MRI offers practical advantages for patients requiring both PET and MRI examinations for oncologic assessment by providing both modalities within a single appointment and imaging session. Radiation exposure is also reduced because CT is not used in the imaging protocol.

Finally, PET-MRI allows accurate, temporally and spatially aligned multiparametric imaging that combines high-contrast anatomic MR images with the quantitative power of molecular imaging of both PET and MRI, including DWI, perfusion MRI, and MR spectroscopy. This potential creates numerous opportunities for characterizing tumor biology across all of the dimensions of imaging offered by PET and MRI.

## Cystic renal masses

Incidentally discovered renal cysts are commonly found on cross-sectional imaging studies. Strict imaging criteria have been developed by Bosniak to categorize renal cysts as benign, malignant, or indeterminate, and to guide in the management of these lesions. The Bosniak Classification (Table 123.1) of renal cystic was first described in 1986 [35] but has undergone several modifications [36–39]. Although initially described for lesions found on CT, the criteria can be applied to MRI with overall similar accuracy [40]. In some cases MRI may depict additional septa, thickening of the wall, or enhancement which may lead to an upgraded Bosniak Classification.

**Table 123.1** Bosniak classification of cystic renal masses.

| Category | Features |
|---|---|
| I | A simple water-attenuation cyst with a hairline-thin wall, without septa, calcification, or solid components; no contrast enhancement |
| II | Bosniak type I with a few thin septa or fine calcification in the wall or septa |
| | Sharply marginated, nonenhancing, uniformly high-attenuation lesions of <3 cm |
| IIF | Bosniak type II cystic lesion with minimal enhancement of a hairline-thin septum or wall or minimal thickening of the septum or wall; the cyst might contain calcification that might be nodular and thick but there is no contrast enhancement |
| | Uniformly high-attenuation lesions of >3 cm |
| III | Bosniak type IIF cystic lesion with thickened irregular walls or septa, and contrast enhancement |
| IV | Enhancing soft tissue components or mural nodules |

### Category I

These lesions are benign simple cysts requiring no further diagnostic imaging or follow-up (Figure 123.1). On CT, these lesions must have a paper-thin wall, have entirely fluid attenuation measuring between 0 and 20 HU, and they must demonstrate no enhancement following the intravenous administration of contrast medium. These lesions do not contain septations or calcifications.

### Category II

These lesions are also benign, but are minimally complicated (Figures 123.2–123.4). They may contain a few paper-thin septations. They may also contain fine curvilinear mural or septal calcification. This category also includes hyperattenuating cysts which measure less than 3 cm, are round and sharply marginated with at least one-quarter of the lesions extending outside the renal parenchyma. Most importantly, they must demonstrate uniform high attenuation and no enhancement with intravenous contrast. Cysts that measure between 20 and 40 HU are usually proteinacious cysts and have a density of greater than 40–50 HU are likely to be hemorrhagic. The latter will appear complex on ultrasound. They may appear solid or semisolid due to clot retraction and could be miscategorized by ultrasound.

Dual-energy CT is most helpful in depicting hemorrhagic renal cysts (see Figure 123.3).

Kang et al. attempted to differentiate high-attenuation renal cysts from RCCs on unenhanced CT scans [16]. They retrospectively evaluated the attenuation values and degree of uniformity/heterogeneity in 56 hyperdense

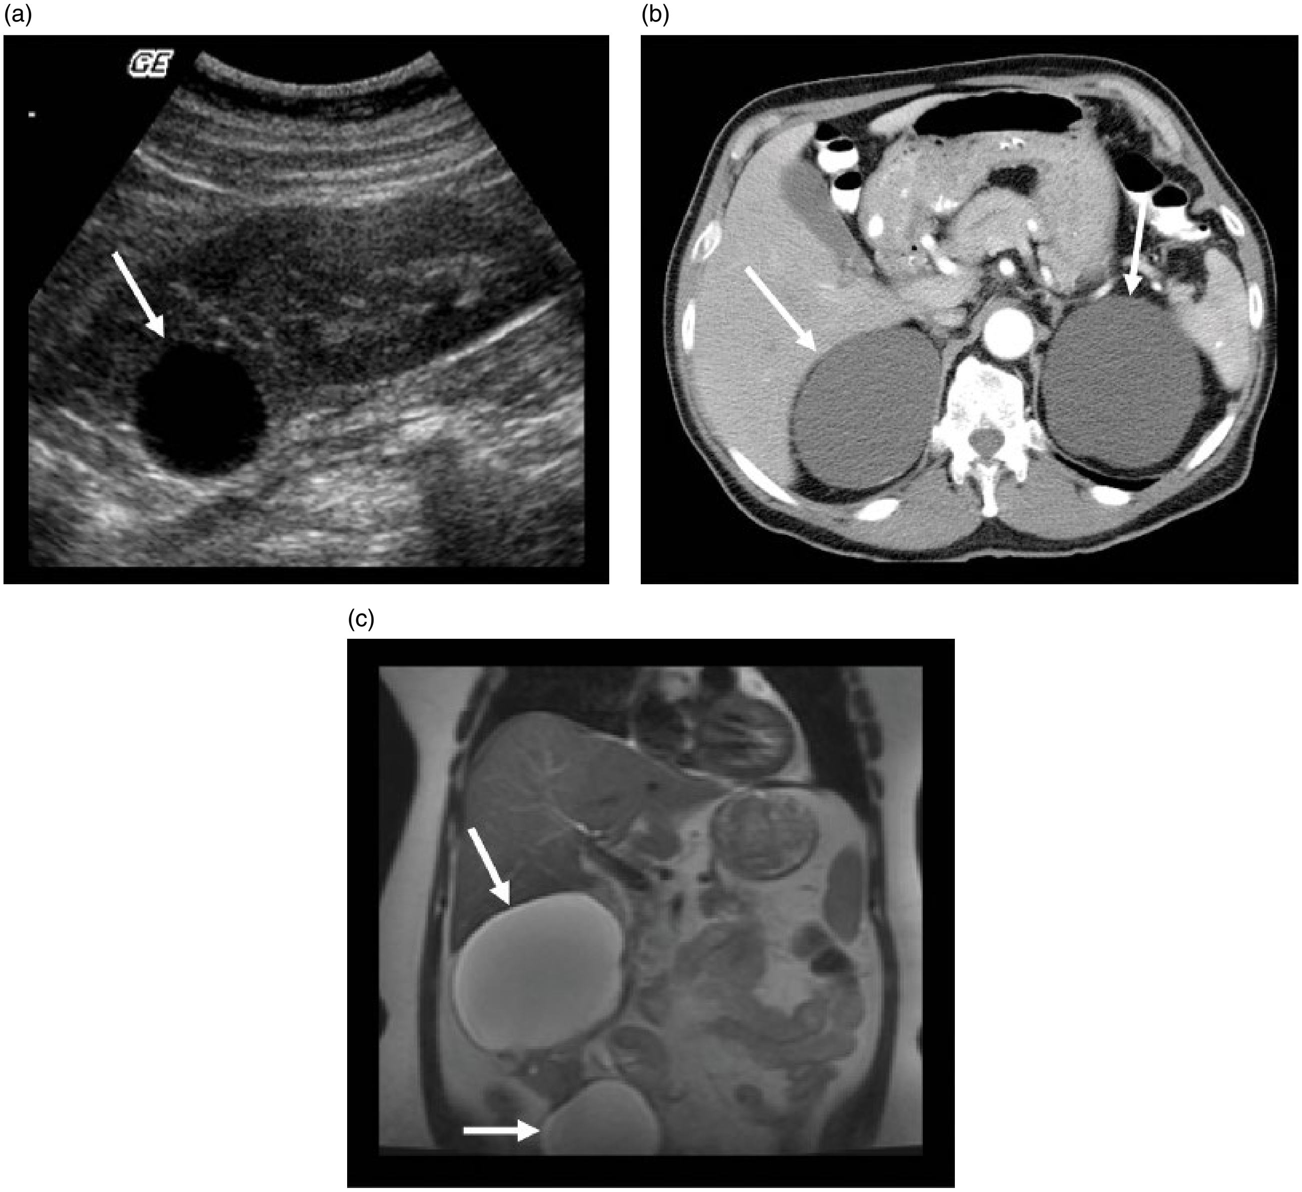

**Figure 123.1** Bosniak type I renal cyst. (a) Longitudinal sonogram shows a well marginated, anechoic cyst (arrow) along the posterior aspect of the upper pole of the right kidney. (b) Axial contrast-enhanced CT scan shows large, bilateral, nonenhancing water density renal cysts (arrows). (c) Coronal T2-weighted MR image shows well-marginated, hyperintense cysts (arrows) with paper-thin walls in the upper and lower poles of the right kidney. Note the absence of mural thickening or nodularity.

renal cysts and 54 RCCs. The mean attenuation for hyperdense cysts was 53 HU and for RCCs was 38 HU, but there was significant overlap when evaluating attenuation values alone. However, when evaluating uniformity versus heterogeneity of the lesion, the authors concluded that a homogeneous, hyperattenuating renal masses with an attenuation of 70 HU or greater, had a 99.9% likelihood of being a benign, high-attenuation renal cyst. Most RCCs in their study had attenuation values lower than those of renal parenchyma (20–30 HU) and were often heterogeneous in attenuation. High-attenuation renal cysts can in many cases be differentiated from RCC on unenhanced CT [16, 41, 42].

### Category IIF

These lesions are likely benign but require a period of observation or follow-up (the F stands for follow-up) to prove their benignity. These lesions may contain an increased number of septa or have minimal septal or

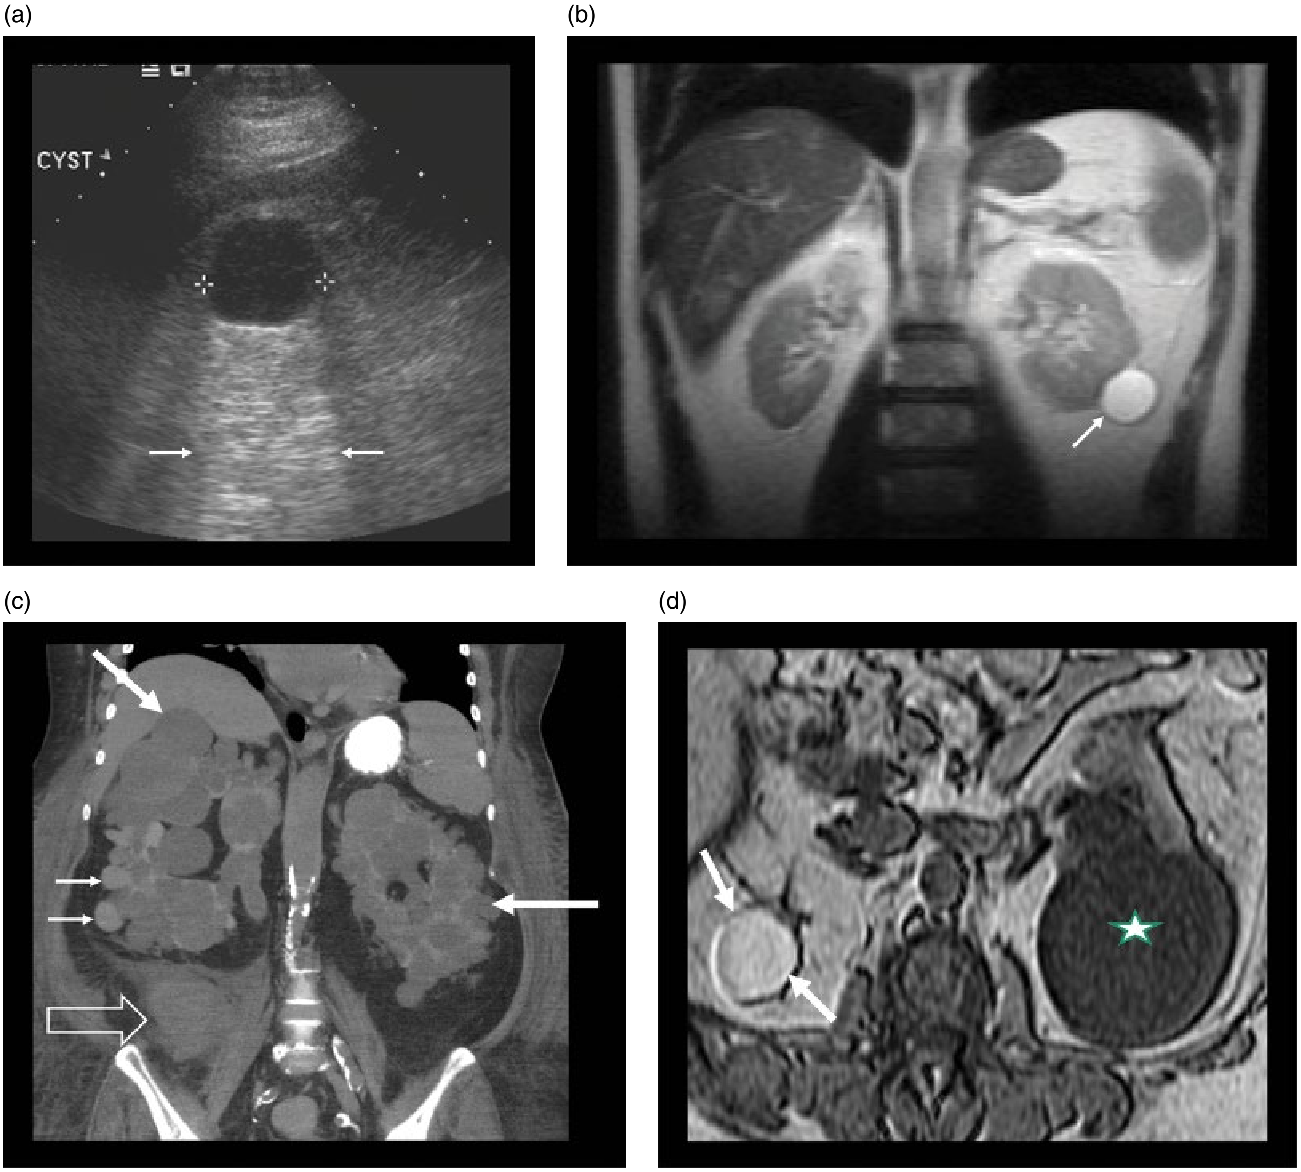

**Figure 123.2** Bosniak type II renal cyst. (a) Transverse sonogram shows a well-marginated cystic structure (cursors) with fine, low-level internal echoes. Note the acoustic enhancement (small arrows) posterior to the cyst. (b) Coronal T1-weighted MR image shows a hyperintense cyst (arrow) indicating the presence of hemorrhage and/or mucin. (c) Coronal unenhanced CT scan in a patient with adult polycystic kidney disease demonstrates multiple simple (type I) (large solid arrows) and hyperdense (type II) (small solid arrows) renal cysts. The high attenuation within the cysts is due to hemorrhage. There is a renal transplant (open arrow) in the right iliac fossa with surrounding hemorrhage. (d) Axial T1-weighted images reveal a hyperintense hemorrhagic (type II) right renal cyst (solid arrows) and a hypointense left simple (type I) renal cyst (star).

mural thickening. Category IIF lesions may contain thick, irregular, or nodular calicifications. When a high-attenuation lesion is completely intrarenal, the smoothness of its wall cannot be assessed. Accordingly, completely intrarenal high-attenuation lesions as well as lesions greater than 3 cm in diameter are included in this category. These lesions may also have a slightly indistinct interface with the adjacent renal parenchyma [33–37].

These lesions should be reimaged with CT or MRI in six months and then annually or every other year for 5 years. Stability over time suggests these lesions are benign, recognizing that some malignant lesions can grow slowly and that cysts can enlarge. Therefore on follow-up imaging their morphologic characteristics must be evaluated in addition to their size. If there is any increase in the thickness or in the irregularity of the wall or septa, surgical

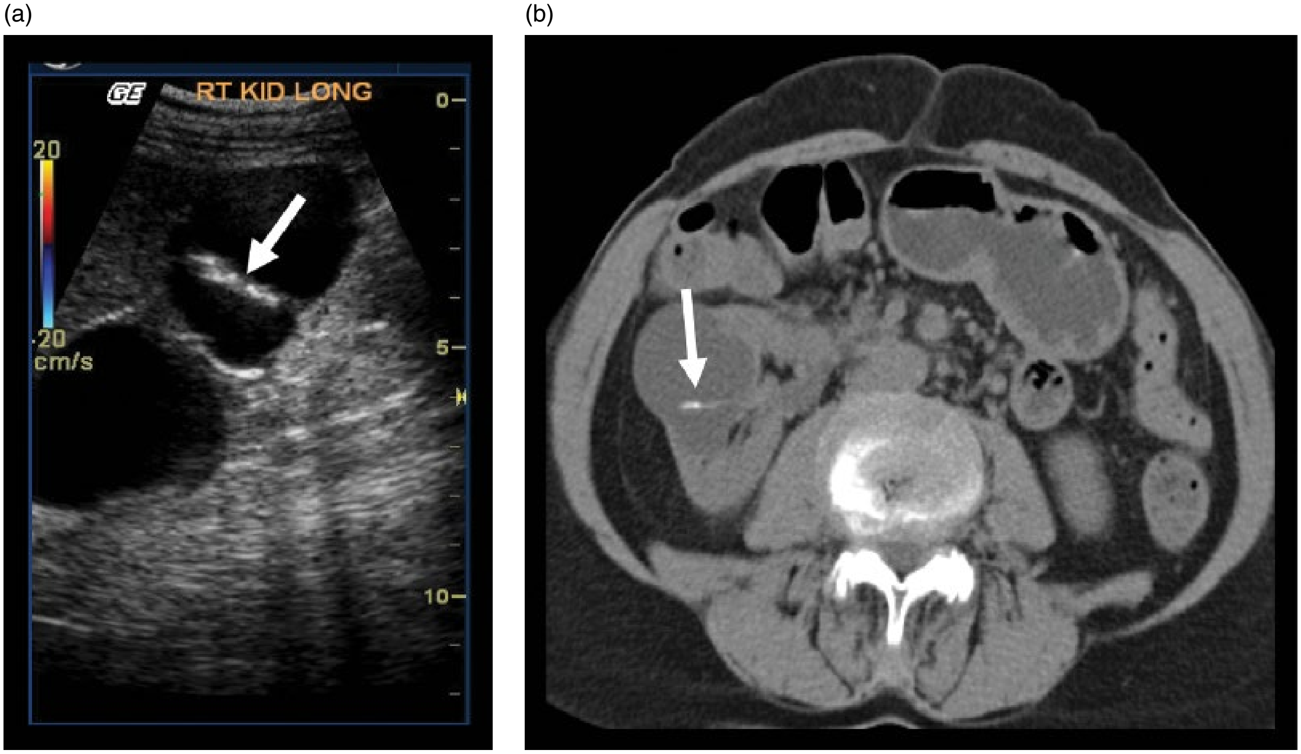

**Figure 123.3** Bosniak type II renal cyst. (a) Longitudinal sonogram shows minimal thickening and calcification of a septation (arrow) in a patient with right renal cysts. (b) This calcification (arrow) is better appreciated on this transverse unenhanced CT scan. This lesion otherwise fulfills the imaging criteria for a simple cyst.

exploration is indicated. MRI can be particularly useful in evaluating hemorrhagic cystic renal masses and evaluating for the presence of septal or mural enhancement. The introduction of the IIF category in 1993 has prevented unnecessary surgery in large numbers of patients [33–37].

### Category III

These are truly indeterminate lesions which cannot be diagnosed accurately as benign or malignant based on their imaging appearance (Figure 123.5). They contain thick walls or thick septa which demonstrate measurable enhancement. They may contain more extensive, thickened, and irregular calcifications. At pathology, these lesions are multilocular cysts, infected or hemorrhagic cysts, multilocular cystic nephromas, or cystic RCCs. The risk of malignancy in this group has been reported to range up to 59%. Since a significant number of patients with Bosniak type III lesions undergo surgery for ultimately benign disease, some have advocated biopsy in this patient cohort [1, 4, 20].

### Category IV

These lesions are clearly malignant and require surgical removal (Figure 123.6). They may have findings similar to category III lesions but also have enhancing soft tissue components adjacent to the wall or septa. These lesions are usually cystic clear cell carcinomas (accounting for 4–15% of all RCCs), multilocular cystic RCCs, cystic nephromas, and mixed epithelial and stromal tumors [35–38].

## Multilocular cystic nephromas

Multilocular cystic nephroma is a benign renal neoplasm that has biphasic age and sex distribution. Two-thirds of multilocular cystic renal tumors occur in a predominately male pediatric population between three months and 2 years old. Approximately one-third occur in a mostly female population, with a peak incidence in the fifth and sixth decades of life. Presenting symptoms depend on the age of the patient. Children typically present with a painless, progressively enlarging, palpable abdominal or flank mass that has a variable growth rate and may be discovered incidentally. Adults may have a variety of nonspecific signs and symptoms, including abdominal and flank pain, urinary tract infection, and hypertension. Microscopic or gross hematuria can occur in either group cysts. Variable degrees of obstruction of the renal collecting system can occur due to herniation of the tumor, which can lead to urinary tract infection.

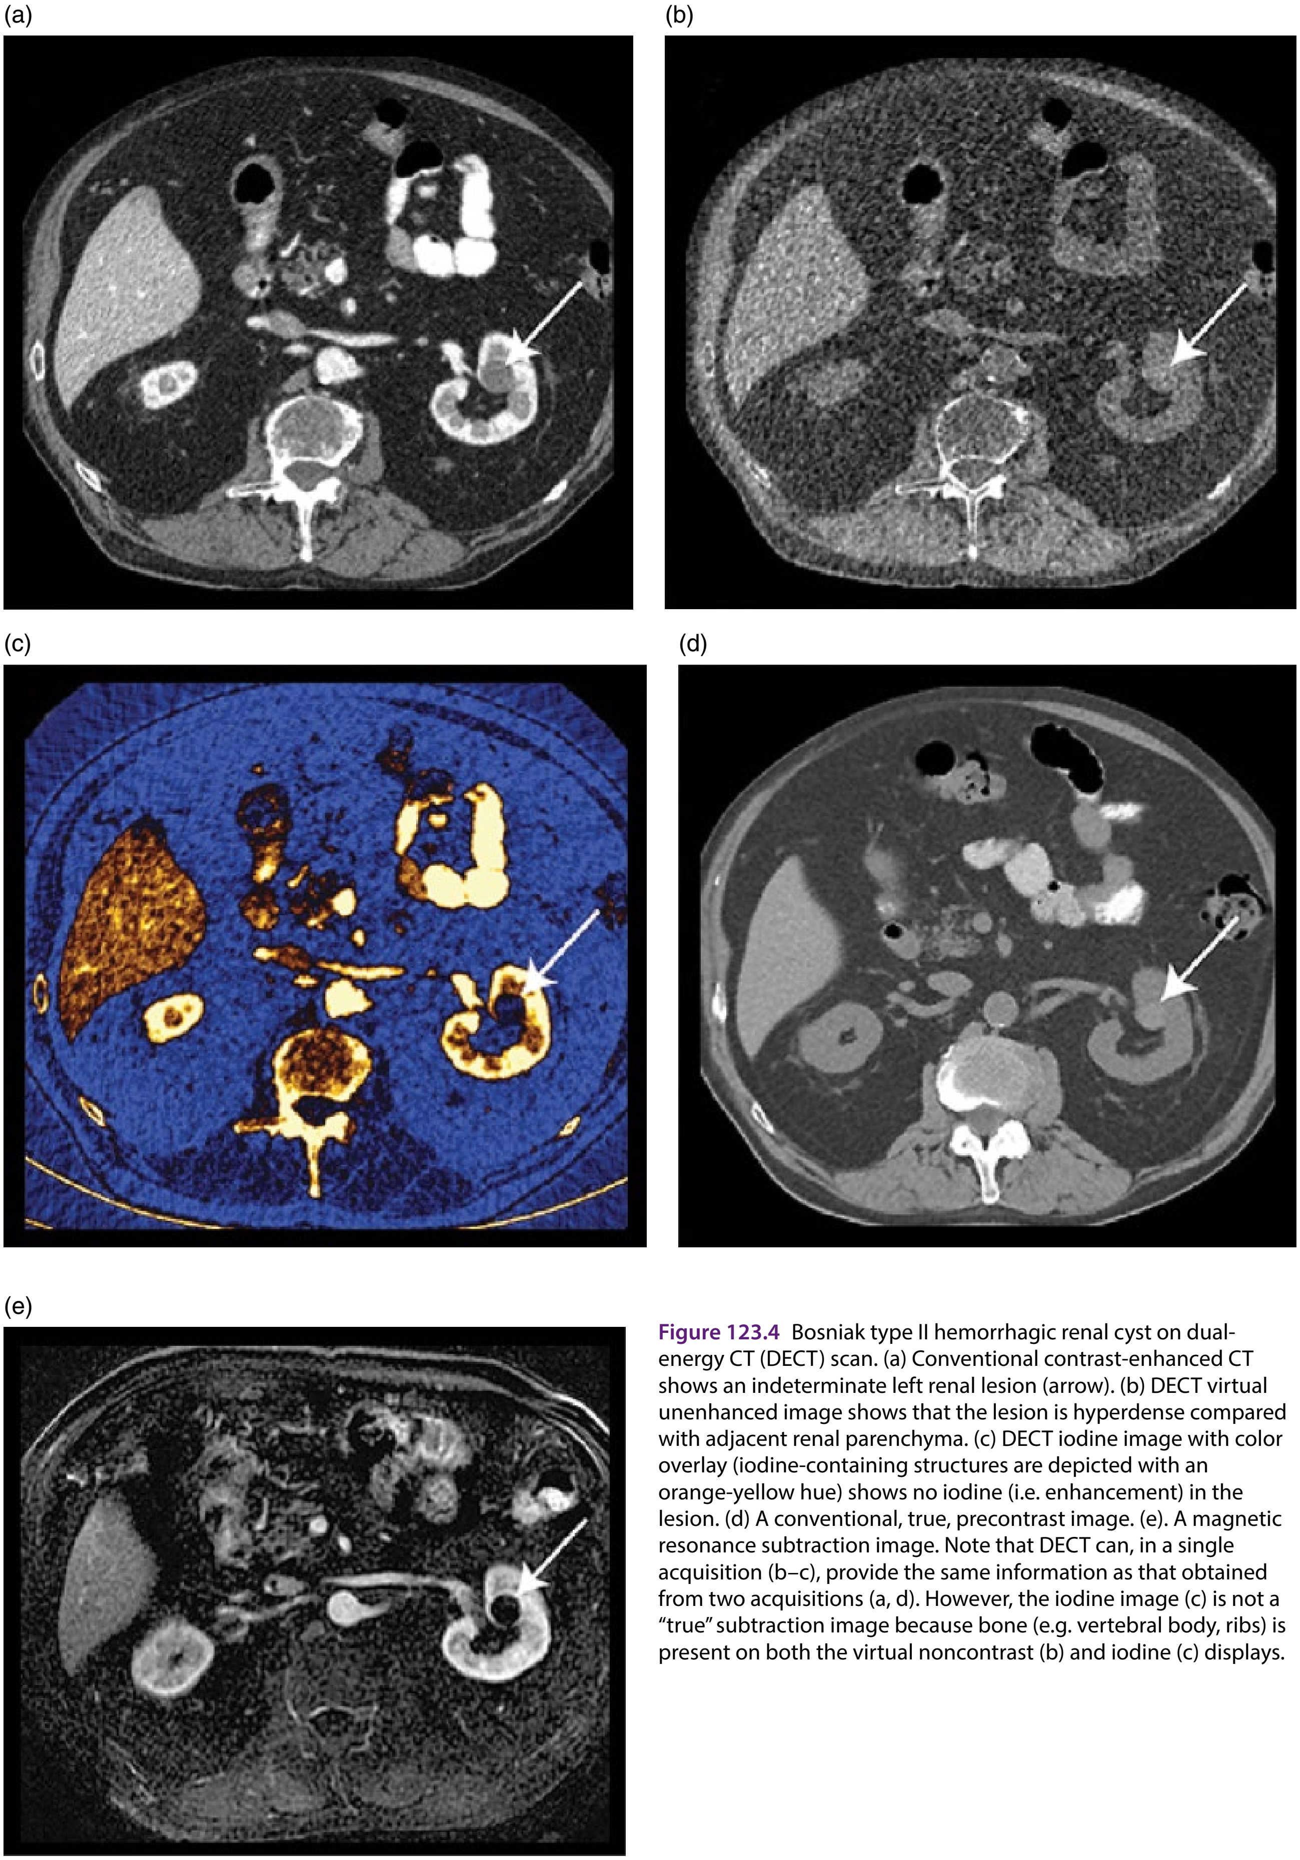

**Figure 123.4** Bosniak type II hemorrhagic renal cyst on dual-energy CT (DECT) scan. (a) Conventional contrast-enhanced CT shows an indeterminate left renal lesion (arrow). (b) DECT virtual unenhanced image shows that the lesion is hyperdense compared with adjacent renal parenchyma. (c) DECT iodine image with color overlay (iodine-containing structures are depicted with an orange-yellow hue) shows no iodine (i.e. enhancement) in the lesion. (d) A conventional, true, precontrast image. (e). A magnetic resonance subtraction image. Note that DECT can, in a single acquisition (b–c), provide the same information as that obtained from two acquisitions (a, d). However, the iodine image (c) is not a "true" subtraction image because bone (e.g. vertebral body, ribs) is present on both the virtual noncontrast (b) and iodine (c) displays.

Most adult patients are asymptomatic and these lesions are discovered incidentally. A complicated cystic lesion is typically identified on cross-sectional imaging (Figure 123.7) [35–38].

## Benign solid renal masses

Most solid renal masses can be accurately characterized with cross-sectional imaging so that biopsy is not necessary [43, 44]. This is particularly true for angiomyolipomas (AMLs) (Figures 123.8–123.10) and RCCs, the two most common solid renal lesions in adults. There are several pseudotumors that can mimic solid renal lesions which must be excluded in order to avoid further evaluation or unnecessary surgery. Occasionally a prominent column of Bertin, a dromedary hump, or persistent fetal renal lobulation can simulate a renal mass on ultrasound, but these can usually be correctly diagnosed with CT or MRI. These pseudolesions have a similar contrast enhancement profile to normal renal parenchyma. In the case of persistent renal fetal lobulation, a normal renal pyramid is present within the center of the bulging portion of renal parenchyma.

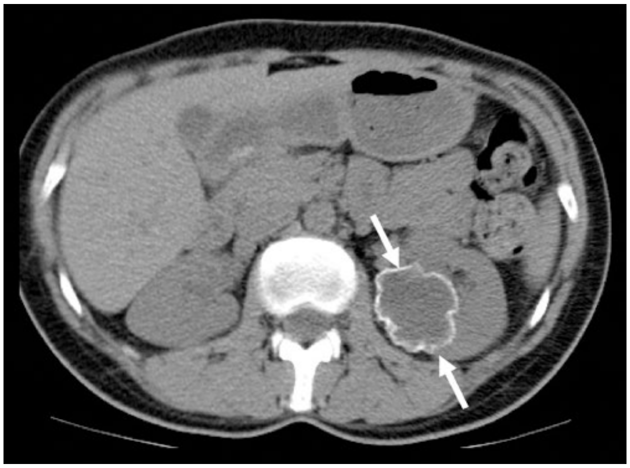

**Figure 123.5** Bosniak type III cystic renal lesion. Axial unenhanced CT scan shows thick, irregular calcification (arrows) associated with a low-density renal mass. This lesion proved to be a renal cell carcinoma.

Benign lesions that can simulate a renal neoplasm include focal acute pyelonephritis [45], renal abscess (Figure 123.11) [46], renal hematoma (Figure 123.12) [47, 48], focal xanthogranulomatous pyelonephritis (XPG) [49, 50], arteriovenous malformations (AVMs) (Figure 123.13) [51–53], and acute focal infarction (Figure 123.14). Extremely rare entities such as extramedullary renal hematopoiesis, tuberculoma related to therapy for bladder cancer, and splenorenal fusion can also mimic a renal mass.

Often the clinical history or additional findings on CT can be useful in making the correct diagnosis. For example, stranding in the adjacent perinephric fat should raise suspicion for acute pyelonephritis, although there are rare infiltrative renal tumors such as medullary RCC that can demonstrate this finding. In the case of focal pyelonephritis, there is a wedge-shaped area of heterogeneous hypoattenuation with no well-defined wall and no bulge

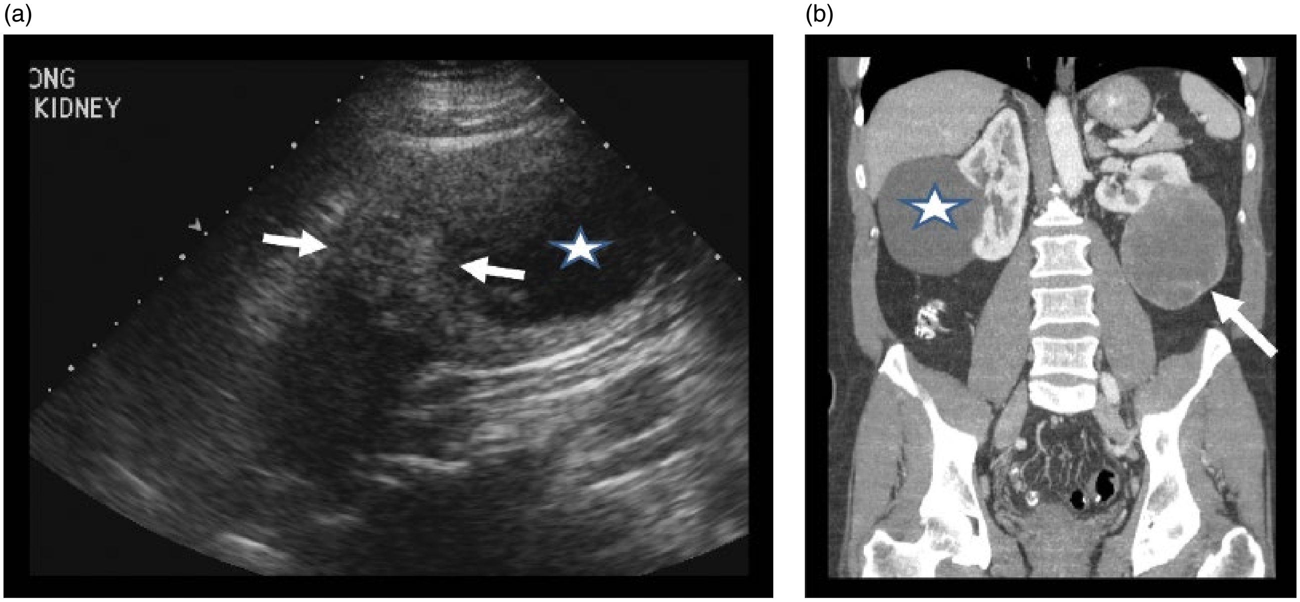

**Figure 123.6** Bosniak type IV cystic renal lesion. (a) Longitudinal ultrasound of the left kidney shows a lower pole mass that has mural thickening superiorly (arrows) and a more cystic component inferiorly (star). (b) Coronal reformatted contrast-enhanced CT image shows mural and septal enhancement (arrow) of this mass. Note the Bosniak type I cyst at the lower pole of the right kidney (star).

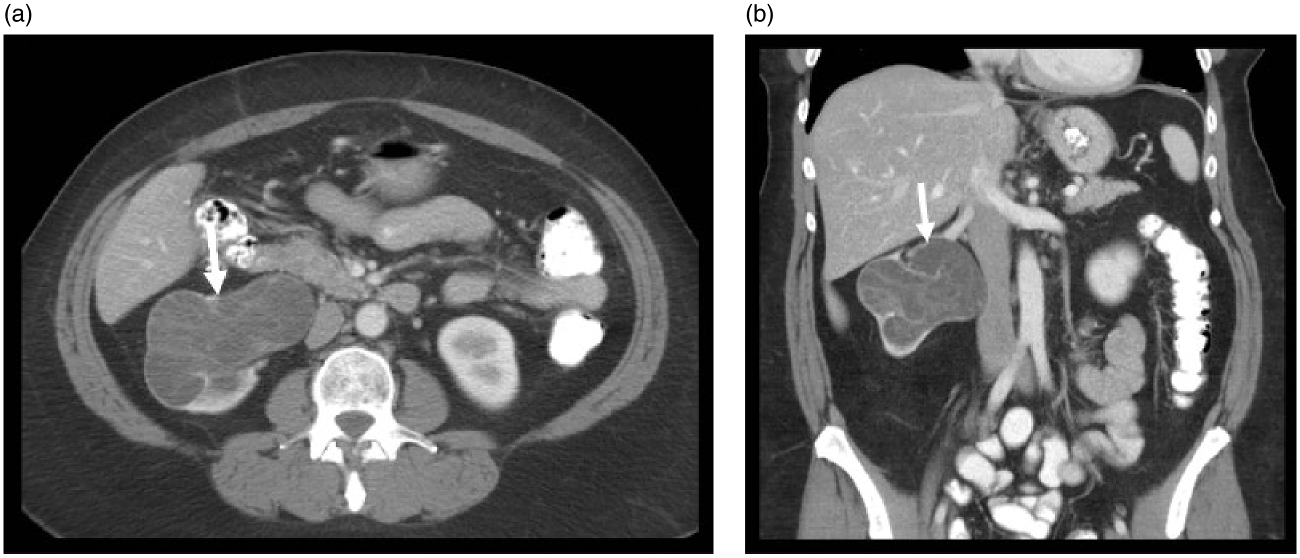

**Figure 123.7** Multilocular cystic nephroma: CT features. Axial (a) and coronal reformatted (b) images disclose a multiseptated central cystic mass (arrows) involving the left renal pelvis.

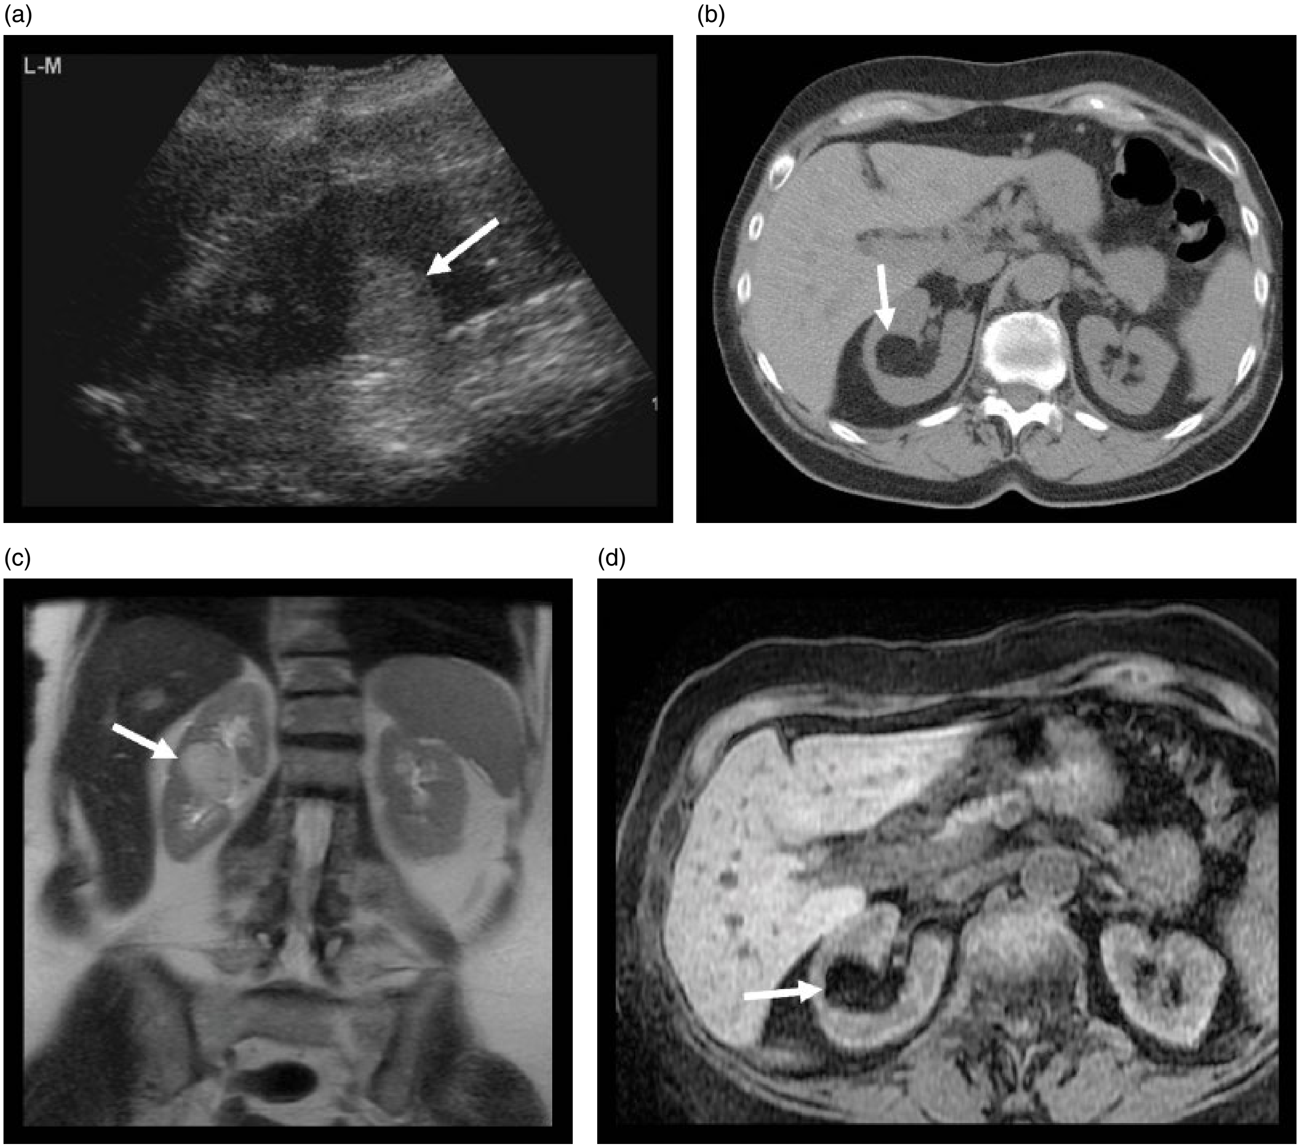

**Figure 123.8** Renal angiomyolipoma: imaging features. (a) Longitudinal sonogram demonstrates a well-marginated uniformly hyperechoic renal mass (arrows). (b) Axial unenhanced CT scan shows a well-circumscribed, fat-containing right renal mass (arrow), with a density of −85 HU. (c) This mass is hyperintense on this T1-weighted coronal MR image. (d) This lesion (arrow) shows signal dropout on this axial, fat-suppressed MR image.

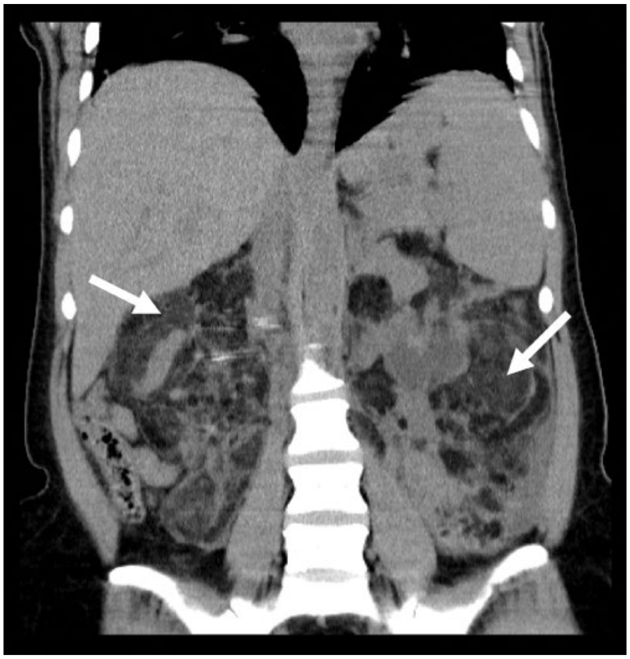

**Figure 123.9** Multiple renal angiomyolipomas replace the kidneys in this patient with tuberous sclerosis. Coronal reformatted CT scan shows multiple fat-dense renal lesions (arrows).

on the renal surface, features which help distinguish it from RCC. If there is still a question about the nature of the mass a follow-up scan showing healing and resolution can be helpful [45, 46].

AVMs can be intraparenchymal (see Figure 123.13) or in the renal sinus, but observing that the mass enhances to the same degree as the renal artery should be the clue to the correct diagnosis on CT and MRI. The feeding renal artery to the AVM is often enlarged as well. On gray-scale ultrasound an AVM appears as an anechoic structure that fills with color on color Doppler sonography. On noncontrast MRI scans, AVMs manifest as intralesional flow voids that show early enhancement, abnormal tortuous vessels, and an early draining vein following the intravenous administration of contrast medium [51–53].

Focal XGP can be difficult to distinguish from an RCC, but the presence of a staghorn calculus, which occurs in 70% of cases, is a helpful clue. There may be low attenuation within the associated collecting system mass due to presence of lipid-laden macrophages. This disorder typically occurs in diabetic patients [49, 50].

When renal hematomas (see Figure 123.12) occur in the setting of trauma, the diagnosis is usually straightforward. However, renal hematomas can also occur spontaneously in patients who are anticoagulated, have a coagulopathy, or vasculitis. Typically, radiologists are not privy to this information to assist in the diagnosis. On noncontrast CT images, the hematoma may be hyperdense, and there should be no contrast enhancement. Occasionally, active extravasation of contrast material may be visualized. Hematomas are more easily diagnosed with MRI because of the typical signal characteristics of blood.

Subepithelial renal pelvic hematomas (Antopol–Goldman lesions) are a rare cause of a heterogeneously dense or hyperdense masses in the renal pelvis. They do not show contrast enhancement and may cause worrisome extrinsic compression on the renal collecting system. These lesions are often confused with renal pelvic malignacies, and in most cases, patients underwent nephrectomy for what was thought to be malignant disease [1].

## Angiomyolipomas

AMLs are the most common benign mesenchymal renal neoplasms and are composed of fat, smooth muscle, and vascular tissue [54–57]. They typically occur sporadically in middle-aged patients, and are four times more common in females than males. Tuberous sclerosis, an autosomal dominant disease, accounts for 10–20% of all individuals with AML. The lesions in tuberous sclerosis are seen in younger patients and with equal frequency in males and females. The lesions in the sporadic form are usually less than 5 cm in diameter, however AMLs seen in tuberous sclerosis can be much larger and are often multiple and bilateral [58]. Although benign, AMLs often increase in size over time and larger tumors have a propensity to bleed (see Figure 123.8). AMLs have a greater tendency to grow when they are multiple.

The imaging appearance varies according to the proportion of fat, muscle, and blood vessels. Since 95% of AMLs contain macroscopic fat (see Figures 123.7–123.10), the diagnosis can usually made with confidence on unenhanced CT when there are one or more regions of fat in a noncalcified renal lesion. They typically are well marginated, cortical in location, and predominantly fatty lesions with heterogeneous regions of soft tissue attenuation interspersed throughout the mass. Although the soft tissue components of the mass may enhance with intravenous contrast, this is not a dominant feature of most AMLs [54–58].

Sonographically, small angiomyolipomas appear as uniformly hyperechoic lesions (see Figure 123.8). Unfortunately this sonographic appearance is also seen in 32% of small (<3 cm) RCCs. Echogenic carcinomas are more likely to have a hypoechoic rim and cystic areas, while AMLs are more likely to demonstrate acoustic shadowing and no hypoechoic rim. These findings are not sufficiently sensitive or specific to confidently make the diagnosis so that CT or MRI is required for further evaluation. Larger AMLs are more complex on ultrasound and difficult to diagnose. On MRI (see Figure 123.8), most AMLs can be readily

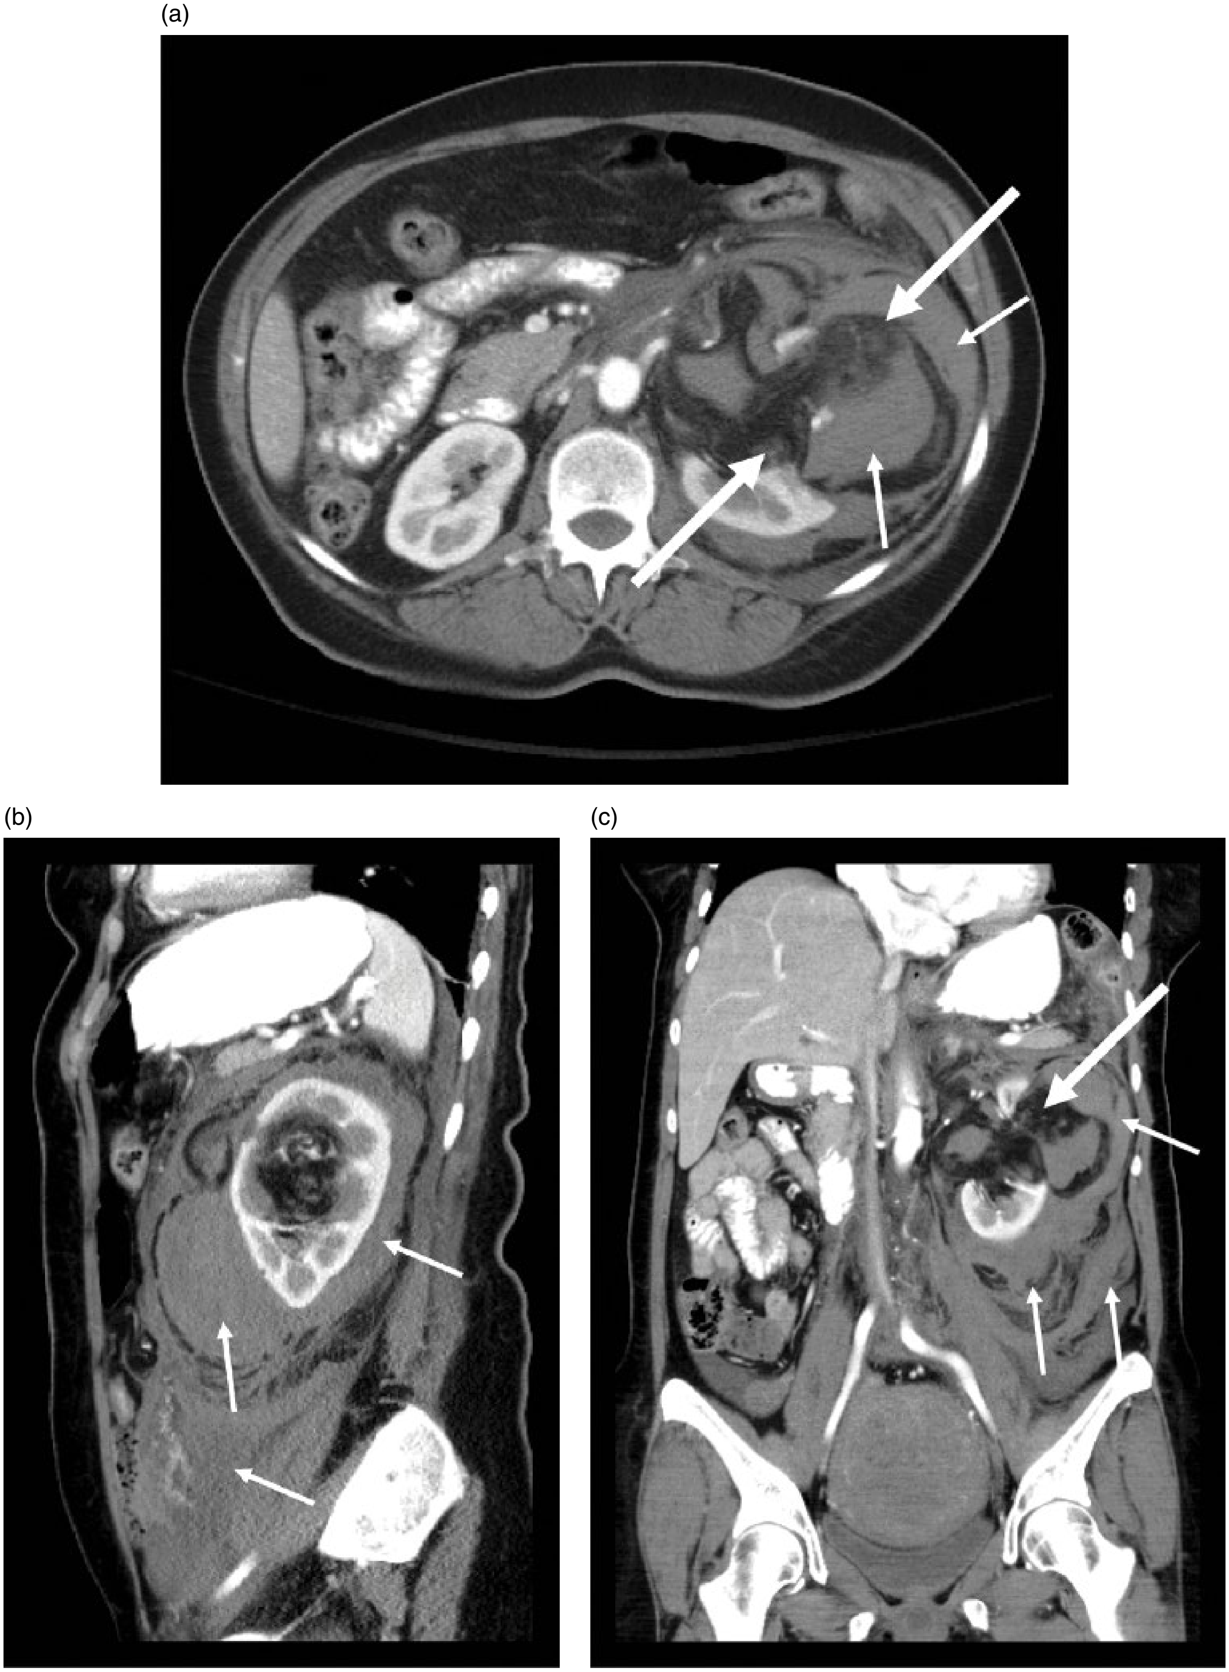

**Figure 123.10** Hemorrhagic angiomyolipoma: CT features. Axial (a), sagittal (b), and coronal (c) CT images show a large fat-containing angiomyolipoma (large arrows) associated with a large renal and perirenal hematoma (small arrows).

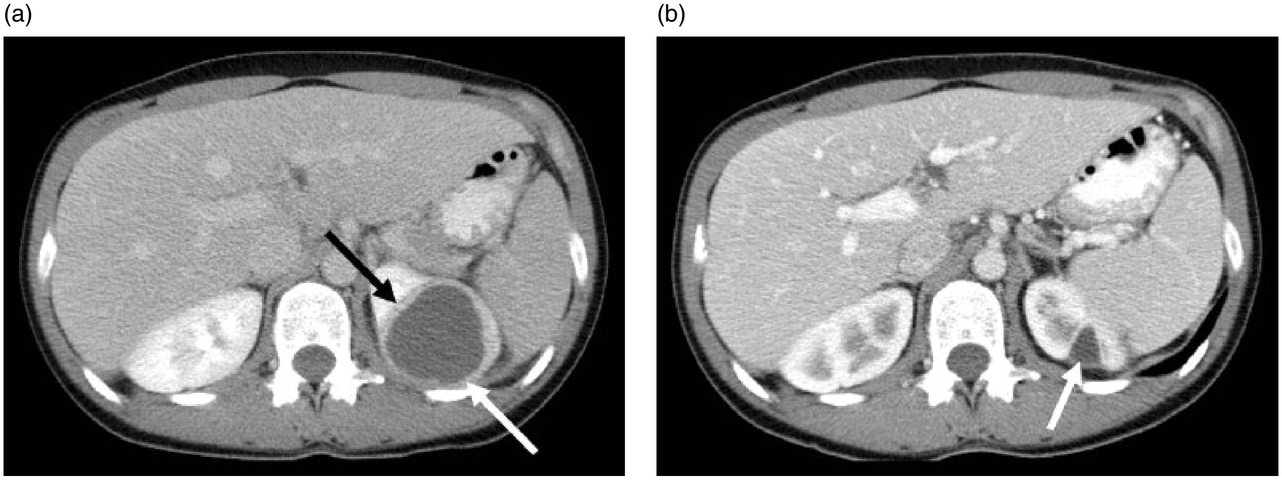

**Figure 123.11** Renal abscess causing a low-density renal mass. (a) Transverse contrast-enhanced CT scan shows a thick-walled low-density mass (arrows) at the upper pole of the left kidney. (b) Scan obtained three months after the completion of antibiotic therapy shows a much smaller residual renal mass (arrow).

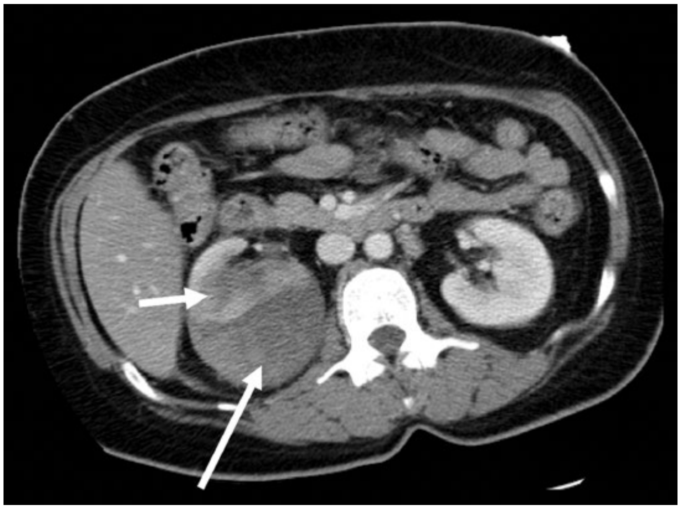
**Figure 123.12** Perinephric hematoma causing a Page kidney. Axial contrast-enhanced CT scan shows a large perinephric hematoma (long arrow) causing compression of the right kidney. Notice the diminished nephrogram of the compressed right kidney (short arrow).



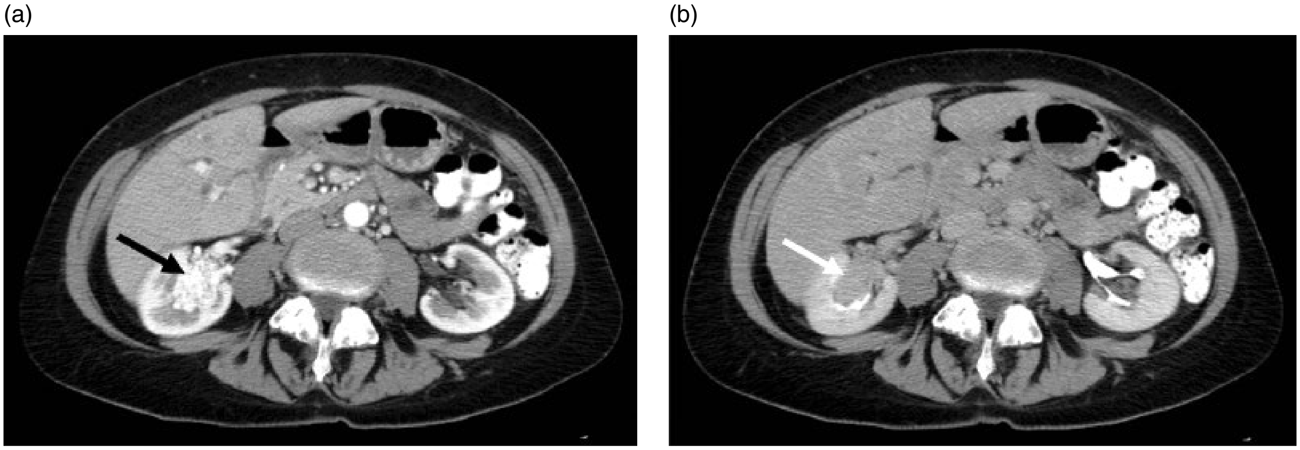


**Figure 123.13** Arteriovenous malformation simulating a renal pelvic mass. (a) Axial CT scan obtained during the corticomedullary phase of enhancement shows multiple tubular enhancing structures (arrow) in the right renal pelvis. (b) On the excretory phase images, they simulate a right renal pelvic tumor (arrow). Parapelvic cysts are present in the left kidney.

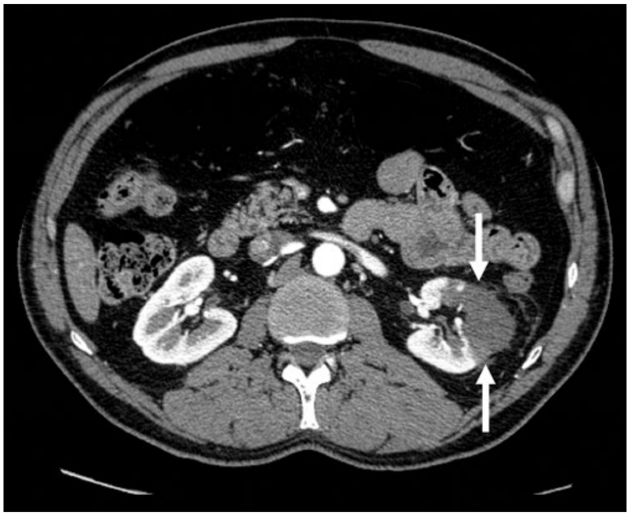

**Figure 123.14** Renal infarct simulating a hypovascular renal mass. Axial CT image depicts a wedge-shaped region of markedly decreased enhancement (arrows) along the lateral aspect of the interpolar region of the left kidney.

characterized with fat-suppression techniques including combined T1-weighted regular (in-phase) and fat-suppressed images or combined T1-weighted in-phase and out-of-phase spoiled gradient-echo sequences [54–58].

The absence of a complete elastin layer in the blood vessels of AMLs predisposes these lesions to aneurysm formation and hemorrhage. The aneurysms commonly seen on angiography may not be appreciated on cross-sectional imaging studies. Hemorrhage is not uncommon. When the lesions bleed, they can present a diagnostic dilemma as the fat may be masked by the hemorrhage. Lesions larger than 3.5–4.0 cm in diameter are believed to have an increased risk of hemorrhage, and are often electively resected with nephron-sparing surgery. In patients with high surgical risk and those with tuberous sclerosis who may have limited renal reserve, selective arterial embolization can be performed [54–58].

There have been reported cases of macroscopic fat in clear cell RCCs. In these cases, extensive calcification is also present in the mass. Since calcification in AMLs is extremely rare, and since fat without calcifications in RCC is extremely rare, a fatty noncalcified renal mass is considered diagnostic of AML. Other fat-containing renal lesions which are extremely rare and are not usually included in the differential diagnosis are lipoma, liposarcoma and, oncocytomas [54–58].

Lipid-poor AMLs (approximately 5%) pose a diagnostic problem in that they appear as solid enhancing masses which have been considered indistinguishable from RCCs based on imaging findings. However, recent studies have suggested that a small (<3 cm) hyperattenuating lesion on noncontrast CT which demonstrates homogeneous enhancement has a strong likelihood of being a benign lesion. This lesion can be further evaluated with MRI to assess for microscopic fat. Percutaneous biopsy can also be performed on these lesions [54–58].

## Oncocytoma

Oncocytomas are benign renal cell neoplasms that account for approximately 5% adult renal epithelial neoplasms in surgical series. They are more common in men than women, and their peak incidence is in the seventh decade. There are some imaging features that suggest the diagnosis of oncocytoma including homogeneous enhancement and a central stellate fibrotic nonenhancing scar in approximately a third of cases. The scar can appear high signal on T2-weighted sequences. Classic CT (Figure 123.15), MRI, and angiographic findings for oncocytoma include a spoke-wheel pattern, a homogeneous tumor blush, and a sharp, smooth rim. Oncocytomas typically do not have perinephric stranding.

Unfortunately, the imaging features of oncocytomas demonstrate considerable overlap with those of RCCs, particularly the chromophobe type, and therefore cannot be reliably used for diagnosis. A central scar and segmental enhancement inversion (in which early contrast-enhanced images show relatively more enhanced and less enhanced intralesional components with inversion of their relative enhancement on later images) are present in at least 10% of cases of both renal oncocytomas and of chromophobe RCCs with no significant difference between the two entities [59–62].

Indeed, oncocytomas often manifest as a complex hypervascular mass that is sometimes associated with adjacent neovascularity and perinephric stranding, findings worrisome for a clear cell carcinoma. Advances in immunocytochemical analysis and cytogenetics may be helpful in distinguishing oncocytoma from RCC in the future, but at the time of this publication, oncocytomas cannot be reliably diagnosed with percutaneous biopsy, and they typically are surgically resected [59–62].

## Other benign solid renal masses

There are other benign solid renal lesions that cannot be reliably distinguished from RCCs, though some have imaging features that may suggest the diagnosis. Papillary adenomas and renomedullary interstitial cell tumors are less than 5 mm in diameter and are common at autopsy [4].

Metanephric adenomas are usually solid and hyperattenuating on noncontrast CT and contain calcification in 20%. Hemangiomas and lymphangiomas typically arise in the renal pyramids or pelvis. Leiomyomas commonly

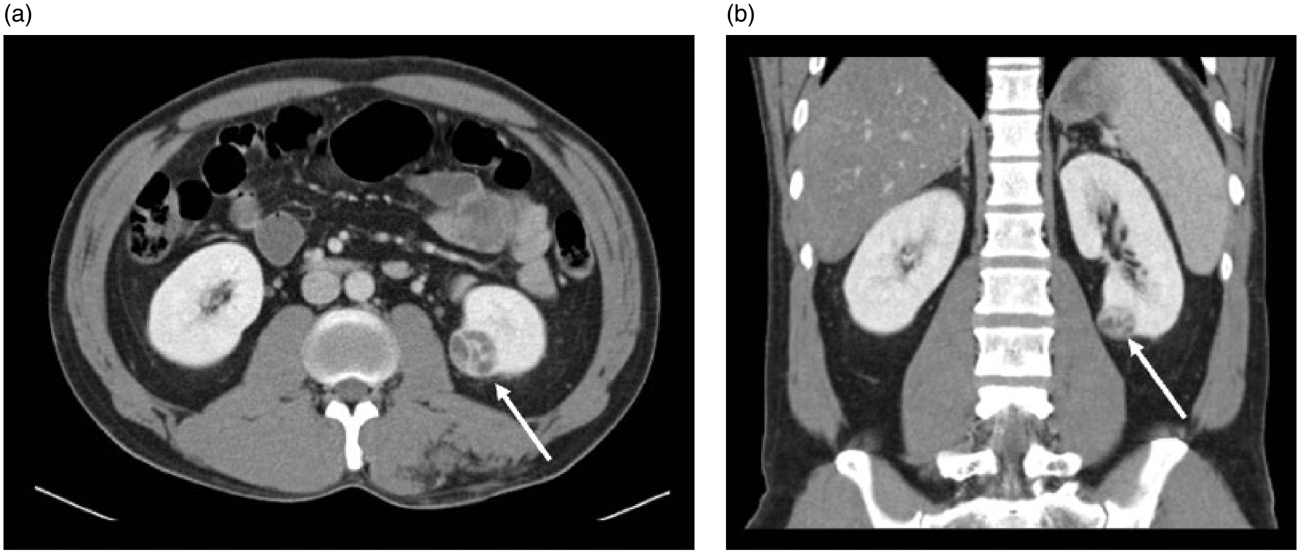

**Figure 123.15** Renal oncocytoma: CT features. An enhancing mass with a "spoke-wheel" appearance (arrows) masses is identified at the lower pole of the left kidney on these axial (a) and coronal (b) contrast-enhanced CT scans.

appear as well-circumscribed homogeneous exophytic solid masses that demonstrate uniform enhancement with intravenous contrast. Juxtaglomerular cell neoplasm (reninoma) is an endocrine tumor, which typically occurs in the second or third decades of life, and is twice as common in females than males. Patients present with hypertension and hypokalemia. These lesions typically appear as well-circumscribed cortical tumors less than 3 cm in diameter. Despite the fact that they are such vascular lesions pathologically, they appear hypovascular on contrast CT, possibly due to renin-induced vasoconstriction [4].

Mixed epithelial and stromal tumors consist of solid and cystic areas that may herniate into the renal pelvis. The observation of some of these features may be sufficient to raise the possibility of a benign lesion and in some cases biopsy should be considered rather than immediate surgery [4].

## Renal cell carcinoma

RCC is the eighth most common malignancy and accounts for 2–3% of new cancers in the United States. RCC typically presents in the fifth to seventh decades of life, and is two to three times more common in men and slightly more common in black people than white. The tumors are usually solitary, but can be multifocal in 6–25%. In patients with certain genetic conditions, such as von Hippel–Lindau disease (Figure 123.16), hereditary papillary renal cancer (Figure 123.17), and possibly tuberous sclerosis, multifocality is common. Indeed, multifocal tumors are seen in 87% of patients with von Hippel–Lindau disease [63–65]. RCC is also more common in patients with acquired cystic renal disease, with a three to six times increased risk in patients on long-term dialysis [63, 64]. Because RCCs may be multifocal or bilateral, both kidneys must be scrutinized when staging the lesion prior to surgical or percutaneous intervention.

In recent years, the incidence of RCC has increased due to several factors. In large part this is secondary to the increased incidental detection on imaging studies. Now nearly two-thirds of renal neoplasms are found incidentally compared to approximately 10% in the early 1970s. There has also been an increased rate of survival in patients with RCC, primarily because these lesions are found when small in asymptomatic individuals. There is some evidence suggesting that asymptomatic tumors are smaller and of lower grade and earlier stage than symptomatic lesions. The overall 5-year survival rate is approximately 85% for incidentally detected tumors compared to 53% in symptomatic individuals [63, 64]. Therefore, radiologists have played and continue to play a significant role in finding early cancers and improving patient survival.

According to the 1997 Heidelberg Classification, the most common RCC histologic subtypes are: clear cell adenocarcinoma (65–75%); papillary adenocarcinoma (15%); chromophobe (5%), collecting duct (1%); and unclassified carcinomas (4%). Clear cell RCC, also known as conventional RCC, has a much greater malignant potential than papillary and chromophobe RCCs. Since the prognosis varies among the subtypes of RCC (Box 123.1), being able to distinguish these with imaging can have important clinical implications in the management of certain groups of patients [66–72].

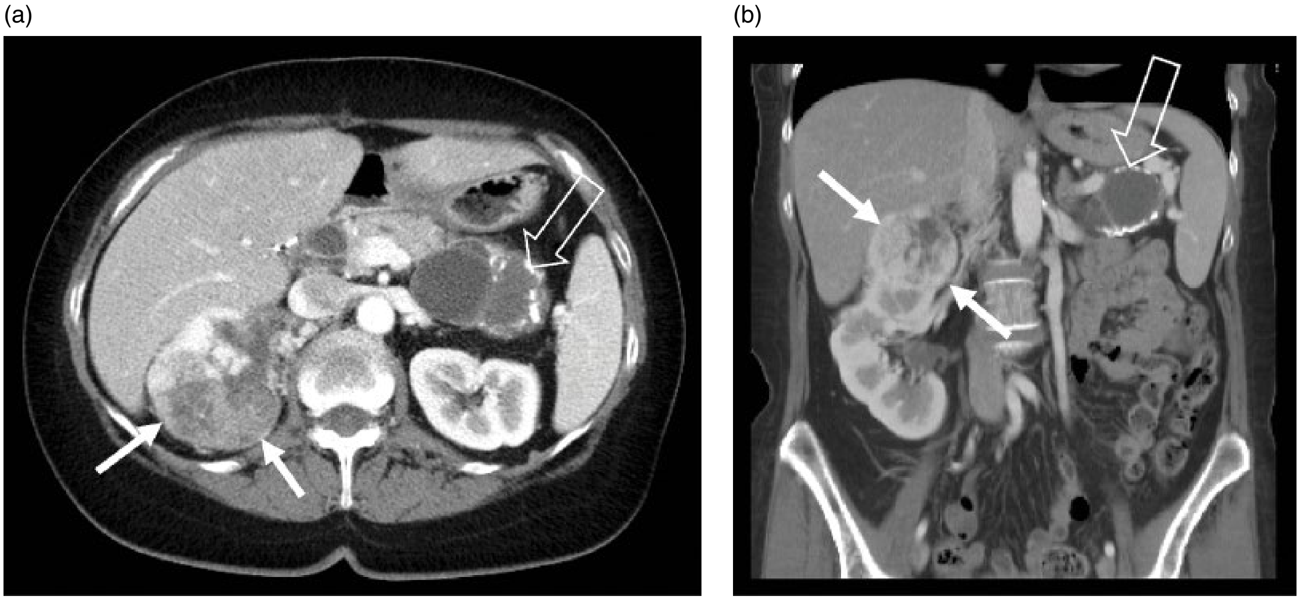

**Figure 123.16** Synchronous renal cell carcinoma and mucinous adenocarcinoma of the pancreas in a patient with von Hippel–Lindau syndrome. Axial (a) and coronal reformatted (b) CT images show a clear cell renal cell carcinoma in the upper pole of the right kidney (solid arrows) and calcified and noncalcified cystic lesions (open arrow) in the pancreatic body and tail. The calcified cystic lesion was a mucinous cystadenocarcinoma.

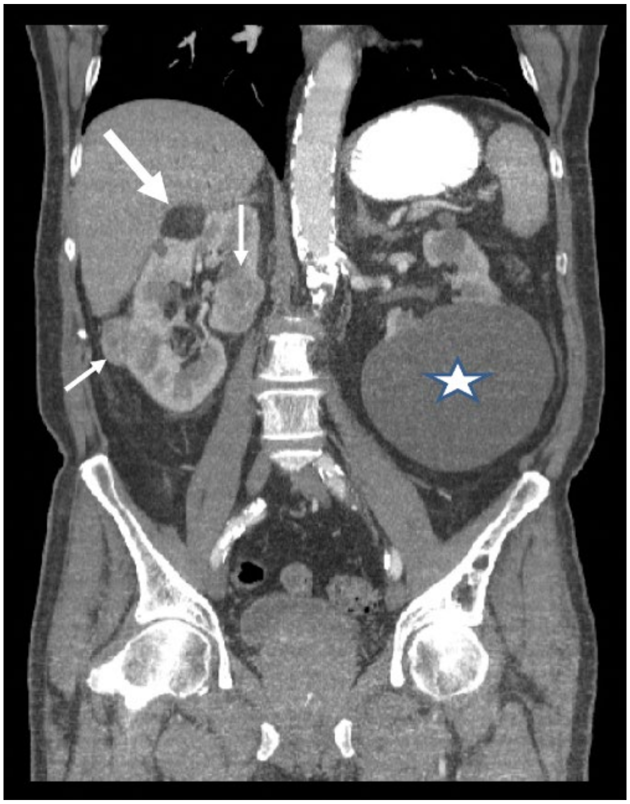

**Figure 123.17** Hereditary papillary renal cancer. Coronal reformatted contrast-enhanced CT image shows synchronous hypervascular neoplasms in the right kidney (small arrows). Note the angiomyolipoma (large arrow) and the large left benign renal cyst (star)

**Box 123.1 Histologic subtypes of renal cell carcinoma.**

- Clear cell renal cell carcinoma
- Multilocular clear cell carcinoma
- Papillary renal cell carcinoma
- Chromophobe renal cell carcinoma
- Collecting duct carcinoma
- Translocation carcinoma
- Renal cell carcinoma associated with neuroblastoma
- Mucinous tubular and spindle cell carcinoma
- Renal cell carcinoma unclassified

Clear cell RCC is the most vascular type of all malignant renal cortical tumors, as shown by its greater degree of enhancement after administration of intravenous contrast material. It most commonly presents with a mixed enhancement pattern of both hypervascular soft tissue components and low attenuation areas that correspond to necrotic or cystic changes. Kim et al. [73] showed that an increase in attenuation of 84 HU in the corticomedullary phase differentiates clear cell from non-clear cell tumors with a sensitivity of 74% and a specificity of 100% [73].

Papillary RCC, on the other hand, demonstrates a low degree of enhancement relative to renal cortical enhancement in either a homogeneous pattern or with low-level peripheral enhancement. A low tumor-to-aorta enhancement ratio or tumor-to-normal renal parenchyma enhancement ratio is highly indicative of papillary RCC [74, 75].

Chromophobe RCCs are more variable in their degrees and patterns of enhancement. Renal medullary carcinoma is a recently described malignant renal neoplasm occurring in patients with sickle cell anemia. It is centered in the medulla and microscopically exhibits reticular, yolk-sac, or adenoid cystic appearance. This neoplasm exhibits aggressive behavior [66–72].

In general, the presence of calcifications in a solid renal mass (Figure 123.18) suggests malignancy. Rarely, a malignant renal tumor may be diffusely calcified [76].

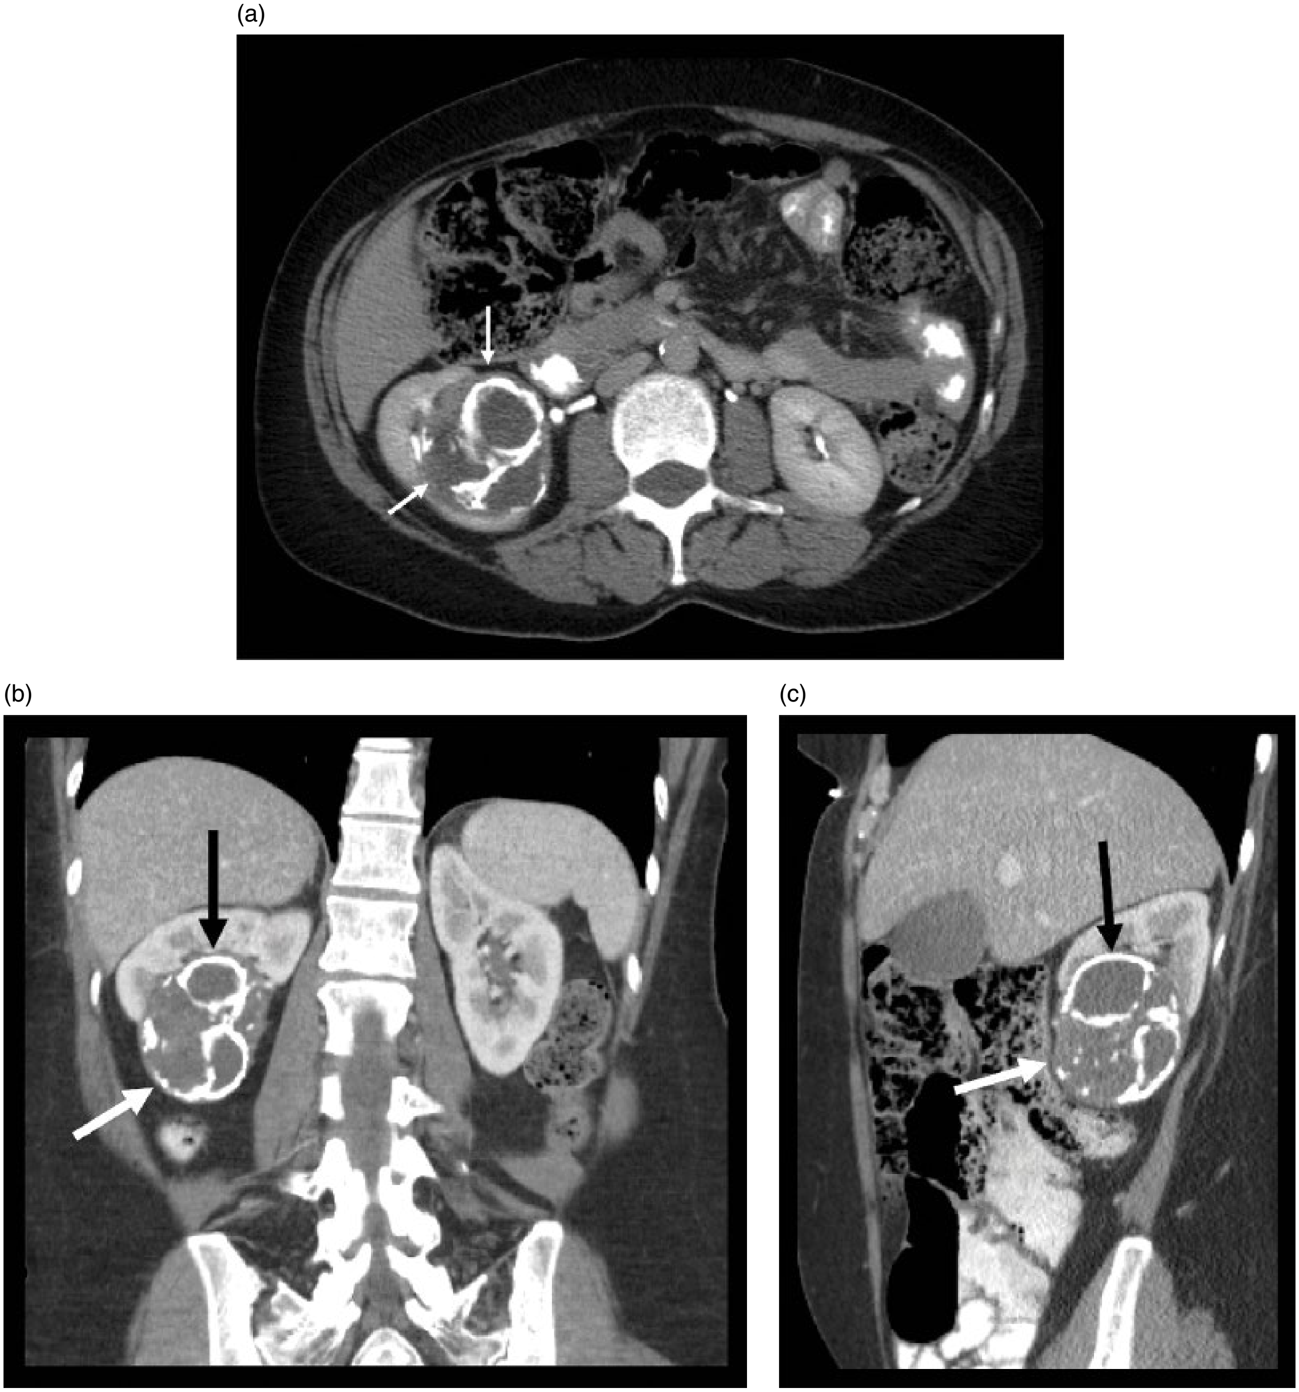

**Figure 123.18** Calcified renal cell carcinoma. Calcified renal cell carcinoma (arrows) is seen at the lower pole of the right kidney on these axial (a), coronal reformatted (b), and sagittal reformatted (c) contrast-enhanced CT images.

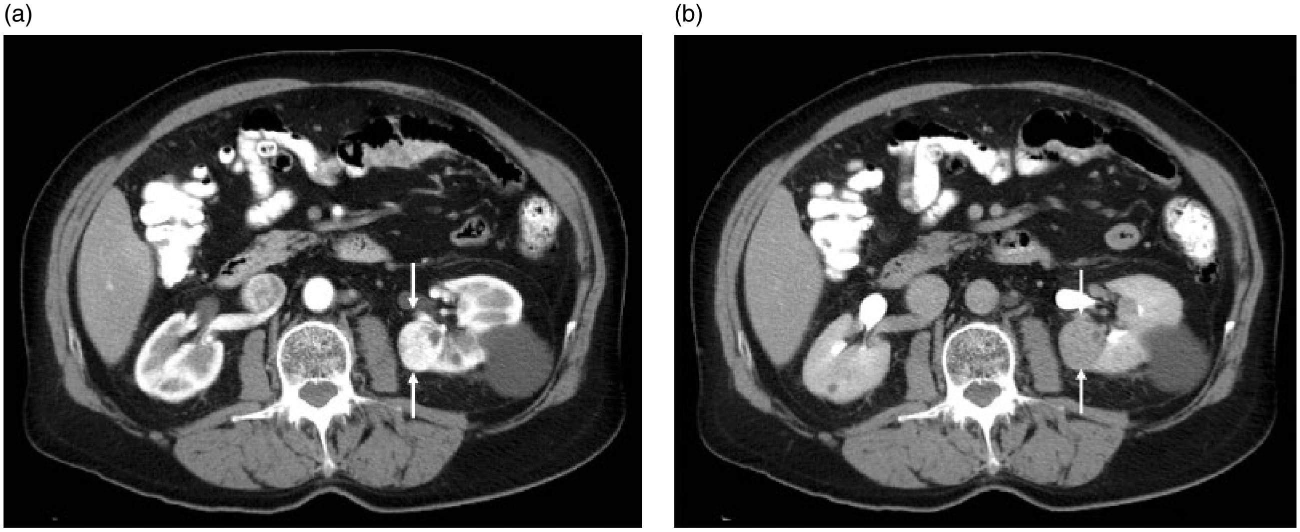

**Figure 123.19** De-enhancement of renal cell carcinoma: CT findings. (a) Scan obtained during the cortical medullary phase shows an enhancing mass along the medial aspect of the left kidney (solid arrows). A simple renal cyst is also present. (b) Three-minute delayed images show that the contrast material has rapidly washed out of the tumor (arrow) and it is now hypodense relative to normal kidney. Bilateral simple renal cysts are present.

RCCs typically show de-enhancement of contrast of >15 HU when the corticomedullary and excretory phases are compared (Figure 123.19).

## Staging renal cell carcinomas

RCCs spread via a number of pathways. They may invade locally, initially through the renal capsule into the adjacent perinephric fat. Upper pole tumors may invade the ipsilateral adrenal gland. More advanced tumors can involve the adjacent musculature or extend beyond Gerota's fascia to involve the liver, spleen, pancreas, duodenum, and colon. RCCs may invade the renal vein and propogate into the inferior vena cava and right atrium. Hematogenous metastases most commonly go to the lungs and bone. RCCs can also spread by lymphatic routes, beginning with renal hilar lymph nodes and then regional para-aortic lymph nodes [77–83],

Accurate preoperative staging of patients with RCC is of paramount importance in selecting the most suitable therapy, guiding surgical intervention, and assessing patient prognosis. The 40-year-old Robson classification of RCC was replaced with the TNM staging system developed in 2002 by the American Joint Committee on Cancer and the International Union Against Cancer (Tables 123.2 and 123.3), because the latter adapts more easily to changing patterns of diagnosis and therapy for RCC. Indeed, it appears that TNM staging is evolving with the advancement of surgical techniques, and is now being challenged by the advent of new, minimally invasive treatment methods such as cryoablation and radiofrequency ablation. MDCT and MRI are superb in T-staging of local tumor extent and M-staging of distant metastasis. However, both imaging tests perform less well with N-staging. Since FDG-PET appears to be unreliable in the detection of RCC and its metastases, research efforts should be directed at finding malignant adenopathy of RCC [77–83].

### T-staging

TNM classes T1 and T2 include all primary RCCs that are confined to the renal capsule (Figures 123.20–123.24). The current TNM classification of 2002 distinguishes between T1a, which defines an RCC with a maximum diameter of 4 cm or less, and T1b, which defines an RCC whose maximum diameter is larger than 4 cm but smaller than 7 cm. Aside from potential differences in prognosis, the most likely reason for the migration of definitions for TNM classes T1 (now T1a and T1b) and T2 lies in the development of new surgical techniques of renal tumor resection [77–83].

It may be difficult to detect subtle invasion of RCC beyond the renal capsule on cross-sectional imaging. Anatomically, the true renal capsule represents the fibrotic outer surface layer surrounding the renal parenchyma. This layer, however, is ill-defined or missing in the renal hilum. Pathologically, RCC induces reactions within the kidney and within the perirenal fat that may make it difficult to distinguish between the true renal capsule and pseudocapsular structures [78, 79].

In terms of T3b and T3c lesions, both MR and MDCT are comparable in assessing tumor invasion of the renal vein and extension into the inferior vena cava either below or above the diaphragm. Extension of RCC tumor

**Table 123.2** American Joint Committee on Cancer (AJCC) TNM Staging System for Kidney Cancer.

| Classification | Description |
|---|---|
| T | Primary tumor |
| Tx | Primary tumor cannot be assessed |
| T0 | No evidence of primary tumor |
| T1 | Tumor ≤7 cm in greatest dimension, limited to kidney |
| T1a | Tumor ≤4 cm in greatest dimension, limited to kidney |
| T1b | Tumor >4 cm but ≤7 cm in greatest dimension, limited to kidney |
| T2 | Tumor >7 cm in greatest dimension, limited to kidney |
| T2a | Tumor >7 cm but ≤10 cm in greatest dimension, limited to kidney |
| T3 | Tumor extends into major veins or perinephric tissues, but not into the ipsilateral adrenal gland and not beyond Gerota's fascia |
| T3a | Tumor extends into the renal vein or its subsegmental branches, or invades the pervicalyceal system, or invades perirenal and/or renal sinus fat but not beyond Gerota's fascia |
| T3b | Tumor extends into the inferior vena cava below diaphragm |
| T3c | Tumor extends into the inferior vena cava above the diaphragm or invades the wall of the inferior vena cava |
| T4 | Tumor invades beyond Gerota's fascia (including contiguous extension into the ipsilateral adrenal gland) |
| **N-classification** | |
| NX | Regional lymph nodes cannot be assessed |
| N0 | No regional lymph node metastasis |
| N1 | Metastasis in regional lymph node(s) |
| **M-classification** | |
| M0 | No distant metastasis |
| M1 | Distant metastasis |
| Mx | Distant metastasis cannot be evaluated |

thrombus above the diaphragm defines TNM class T3c (Figure 123.24 and 123.25) [78, 79].

T4 lesions are characterized by tumor extension of through Gerota's fascia. This assessment may be difficult on cross-section imaging when the fascia is only minimally transgressed.

**Table 123.3** AJCC prognostic groups.

| | |
|---|---|
| Stage I | T1 N0 M0 |
| Stage II | T2 N0 M0 |
| Stage III | T1–T2 N1 M0 or T3 N0–N1 M0 |
| Stage IV | T4 Any N M0 or Any T Any N M4 |

### N-staging

Involvement of regional lymph nodes has several different classifications in the TNM system (Tables 123.2 and 123.3). The most important lymph nodes to evaluate

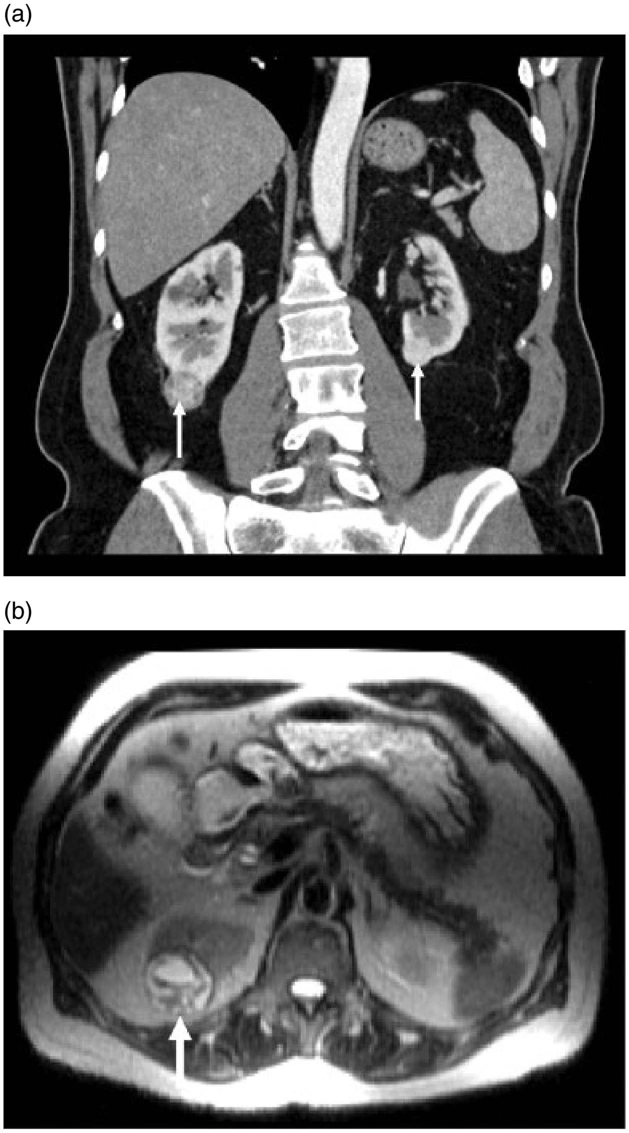

**Figure 123.20** T1a renal cell carcinoma. (a) Coronal reformatted CT image shows bilateral small lower pole renal tumors (arrows) which are limited by the renal fascia. (b) Axial T2-weighted MR images show a complex renal neoplasm (arrows) confined by the renal fascia.

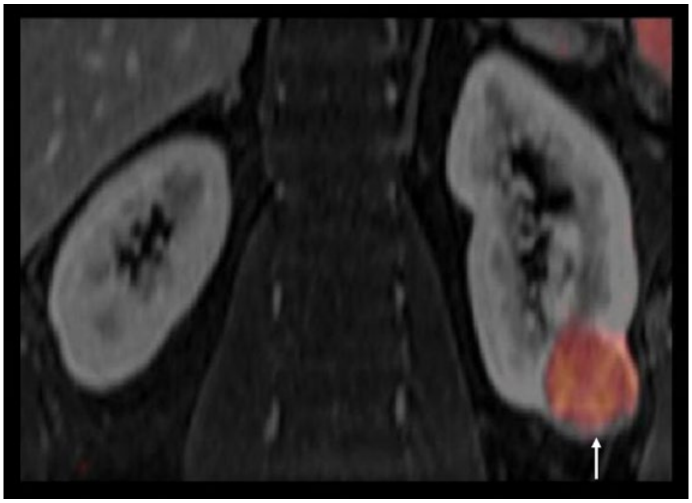

**Figure 123.21** T1a renal cell carcinoma. Coronal PET-MRI image shows a 3 cm mass in the lower pole of the left kidney that is FDG avid (arrow).

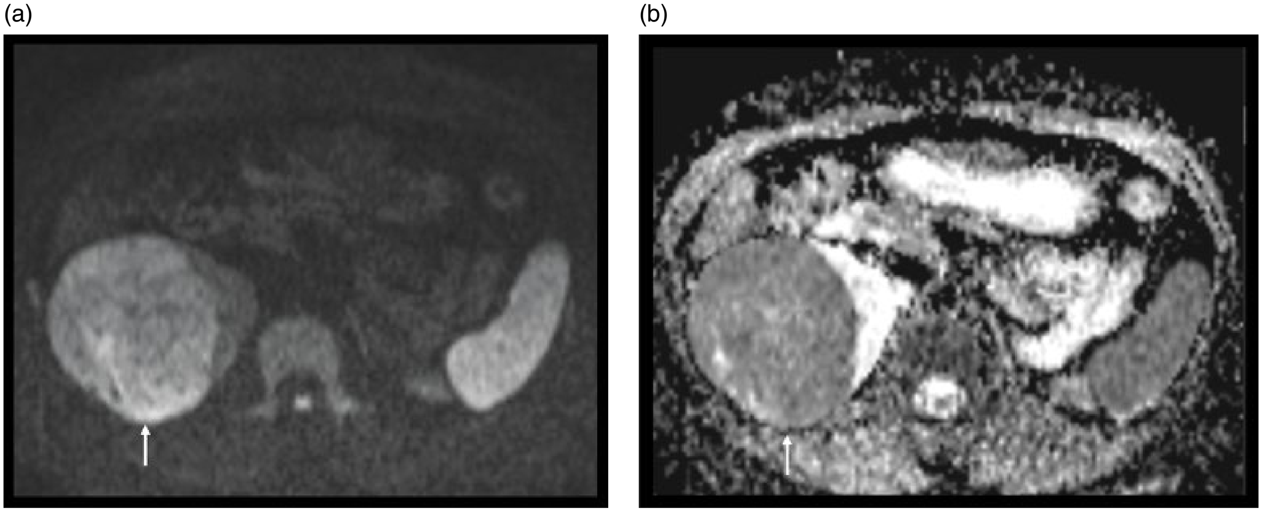

**Figure 123.22** T1b renal cell carcinoma. Functional, diffusion-weighted imaging. Axial diffusion-weighted sequence ($b = 800$) (a) and ADC map (b) reveal restricted diffusion of this neoplasm (arrow) with a low ADC value.

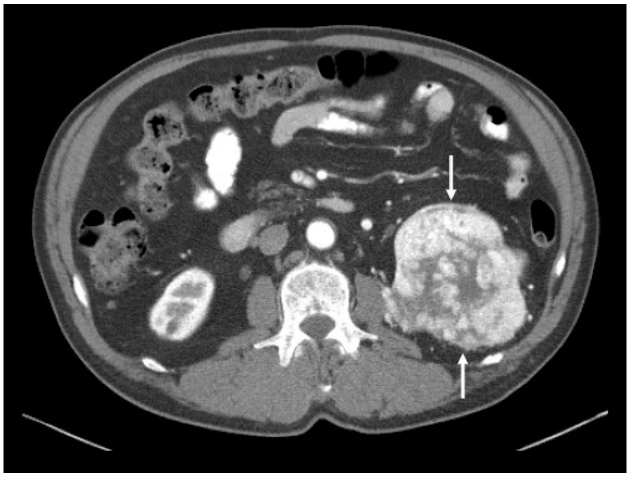

**Figure 123.23** T2 renal cell carcinoma. Axial CT image shows a 7.5 cm enhancing mass (arrows) at the lower pole of the left kidney. It abuts but does not invade the psoas muscle and was confined by Gerota's fascia.

when staging patients with RCC include: nodes along the renal arteries and paracaval lymph nodes for right-sided tumors; para-aortic lymph nodes for left-sided tumors (see Figure 123.24b); and nodes located at the levels of the renal hilum or renal artery. Metastasis in regional lymph nodes without synchronous distant metastasis is found in 10–15% of patients with RCC [83, 84].

As with most neoplasms, the detection of lymph node metastases remain problematic in patients with RCC. Current MDCT and MRI criteria for suggesting adenopathy are lymph nodes that have a short-axis diameter of 1 cm or more and the presence of a prominent node that is more spherical rather than kidney-shaped and has lost its hilar fat. In addition, asymmetric grouping of three or more smaller lymph nodes may also be a sign of lymphatic tumor spread to the renal hilum. Further confounding the accuracy of cross-sectional imaging in detecting

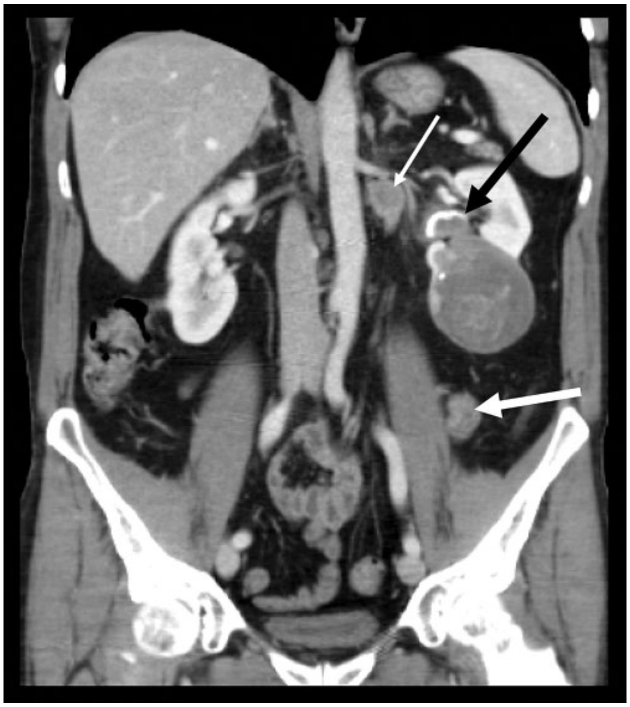

**Figure 123.24** T3a, N2 renal cell carcinoma. Coronal reformatted CT image obtained during the excretory phase shows tumor invasion of the renal pelvis (black arrow). There is left renal hilar adenopathy (small white arrow) and a left paraspinous metastasis (large white arrow).

adenopathy is the fact that more than 50% of enlarged regional lymph nodes exhibit only hyperplastic or inflammatory change pathologically [83, 84].

### M-staging

Distant metastases from RCC, M1 disease, includes all metastases that are either extranodal or involve nonregional lymph nodes. Metastases are most frequently found in the lung (31%) (Figure 123.26), bone (15%) (Figure 123.27), brain (8%), and liver (5%). However, any other organ can be involved [28]. While metastatic RCC requires systemic therapy, surgical excision of the primary lesion appears to be an integral part of systemic therapy for metastatic RCC [85].

MDCT is the preferred means of M-staging patients with RCC because it is superior to MRI in detecting pulmonary metastases. As stated before, FDG-PET at the present time appears too unreliable to recommend its routine use in the staging of RCC [86, 87].

## Transitional cell carcinoma

Urothelial tumors of the renal calices and pelvis account for approximately 7% of primary renal tumors and 5% of all urinary tract neoplasms. Transitional cell carcinomas (TCCs) comprise 90% of pelvicalyceal tumors, with squamous cell carcinoma (which is radiologically indistinguishable from TCC) and adenocarcinomas accounting for 10% of these neoplasms. Patients with previous or current urothelial neoplasm of the bladder are at increased risk of developing TCC of the kidney. Indeed upper tract urothelial tumors have similar risk factors, epidemiologic distribution, and pathologic features. Other risk factors include certain chemical exposures, nonsteroidal anti-inflammatory drug (NSAID) abuse and tobacco use. Because of the multicentric nature of TCC, the urotheluium of the kidneys, ureters, and bladder must be assessed in its entirety prior to treatment to exclude synchronous lesions. During follow-up studies metachronous tumors must be excluded as well [88–98].

The intravenous pyelogram (IVP) has traditionally been the initial screening examination for the detection of upper urinary tract neoplasms for patients with hematuria. The IVP, however, has been shown to miss 40% of upper tract cancers. This technique has been replaced by CTU using MDCT [88–98].

There are three general appearances of TCC on MDCT:

- TCCs may appear as small, hypodense lesions in the renal collecting system (Figure 123.28) demonstrating soft tissue attenuation (<40 HU). On noncontrast images, these tumors have a density of approximately 30 HU, which can be differentiated from urine (0–20 HU), blood clot (50–75 HU), and calculi (>100 HU). There is moderate enhancement with washout on delayed images following intravenous contrast administration, but the degree of enhancement is usually less than that seen in patients with RCC. Some 85% of these lesions are early-stage, superficial papillary neoplasms, that on the excretory phase of CTU appear as a sessile filling defect within the high-density contrast excreted into the renal collecting system. In more advanced cases, the tumor expands the collecting system with compression of the renal sinus fat.
- TCCs may manifest as mural thickening (Figure 123.29), usually symmetric, of the renal collecting system, resulting in circumferential narrowing of the lumen. This may lead to focal caliceal obstruction. The thickened wall may demonstrate enhancement, but a thick enhancing wall can also be seen with infection or with inflammation related to calculi, hemorrhage, recent stent placement or removal, or other surgical manipulation. In some cases biopsy may be necessary to distinguish benign from malignant etiologies.
- TCCs may appear as an infiltrating hypoenhancing renal mass with poorly defined margins. Because TCCs arise from the urothelium, they are more centrally

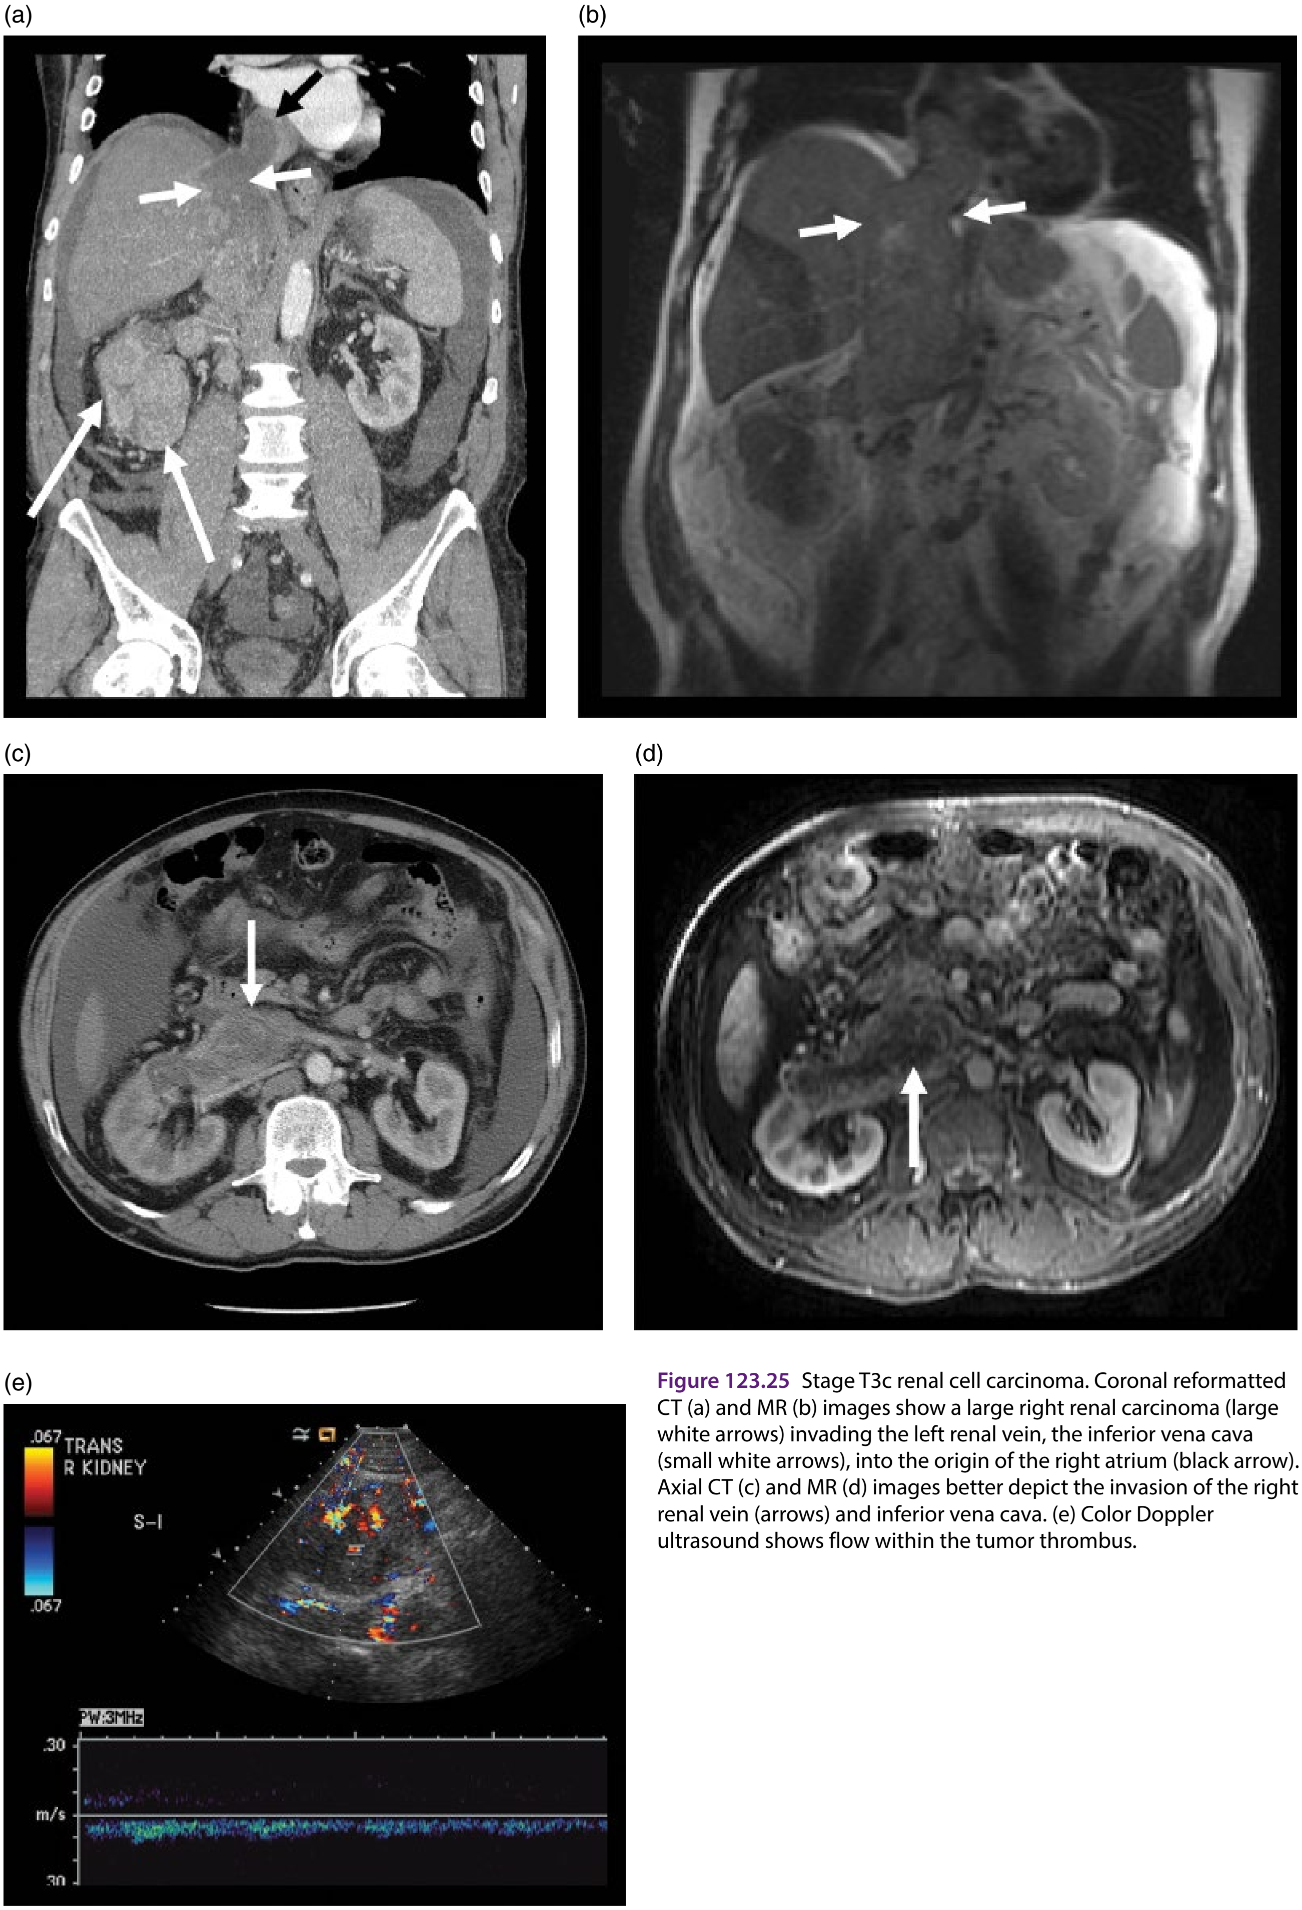

**Figure 123.25** Stage T3c renal cell carcinoma. Coronal reformatted CT (a) and MR (b) images show a large right renal carcinoma (large white arrows) invading the left renal vein, the inferior vena cava (small white arrows), into the origin of the right atrium (black arrow). Axial CT (c) and MR (d) images better depict the invasion of the right renal vein (arrows) and inferior vena cava. (e) Color Doppler ultrasound shows flow within the tumor thrombus.

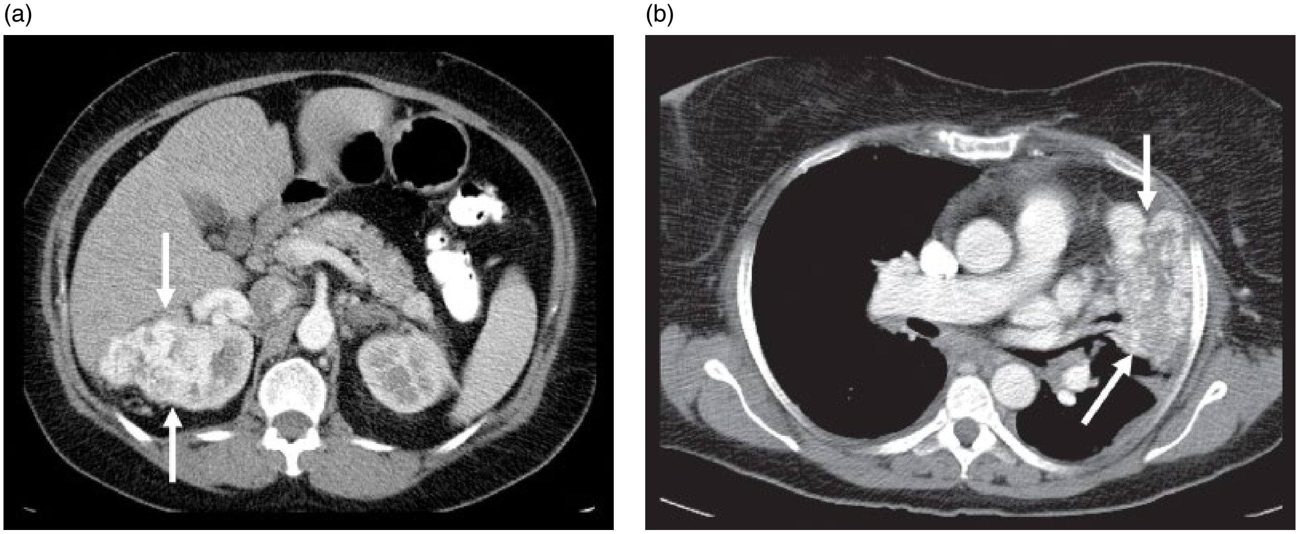

**Figure 123.26** M1 renal cell carcinoma. (a) Axial, contrast-enhanced CT scan shows a hypervascular right renal mass (arrows). (b) Hypervascular metastasis (arrows) is present in the left chest which also invades the pleura.

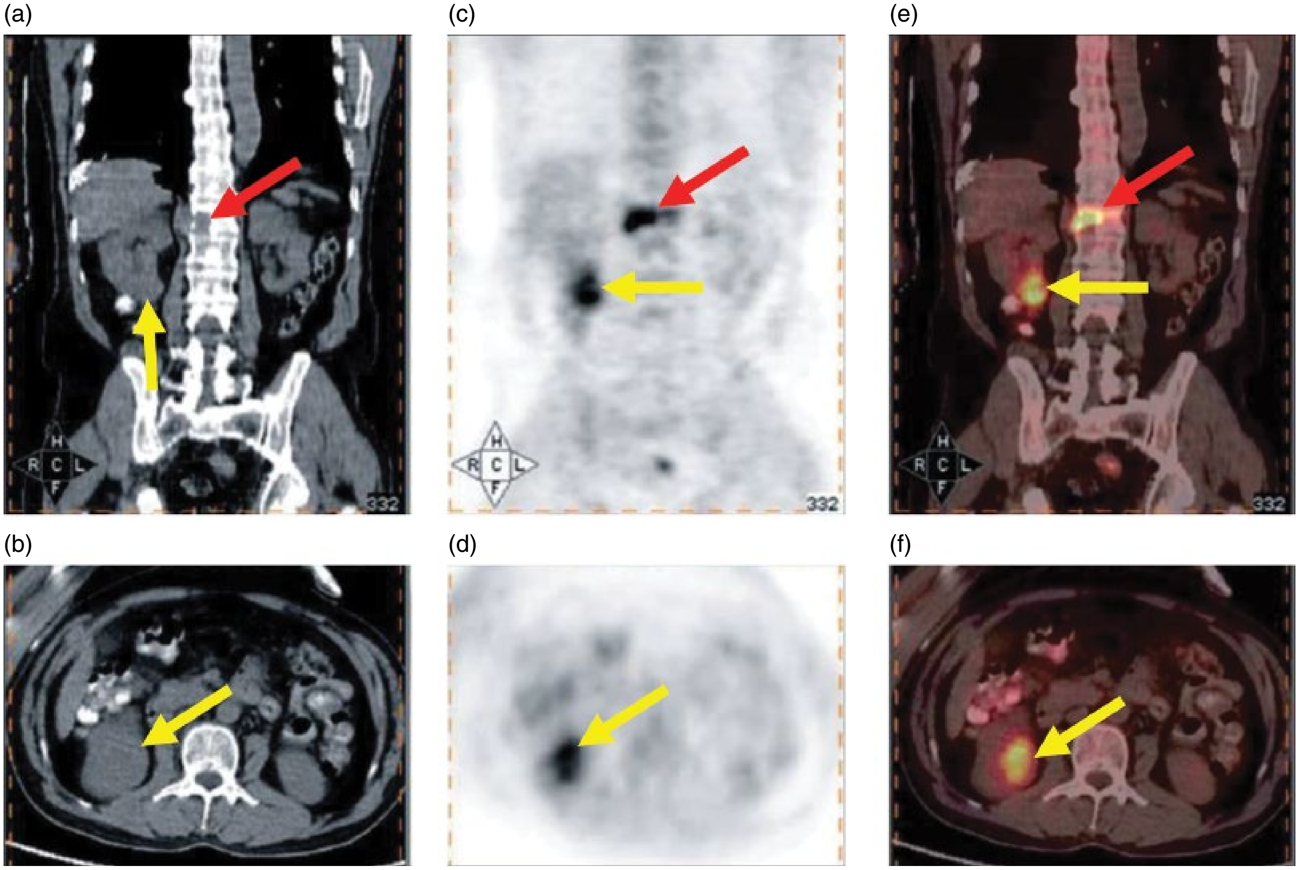

**Figure 123.27** M1 renal cell carcinoma: PET-CT. (a) Coronal CT image. (b) Axial CT image. (c) Coronal PET image. (d) Axial PET image. (e) Fused coronal PET-CT image. (f) Fused axial PET-CT image. Yellow arrows = primary renal cell carcinoma. Red arrows = metastases to the L1 vertebral body.

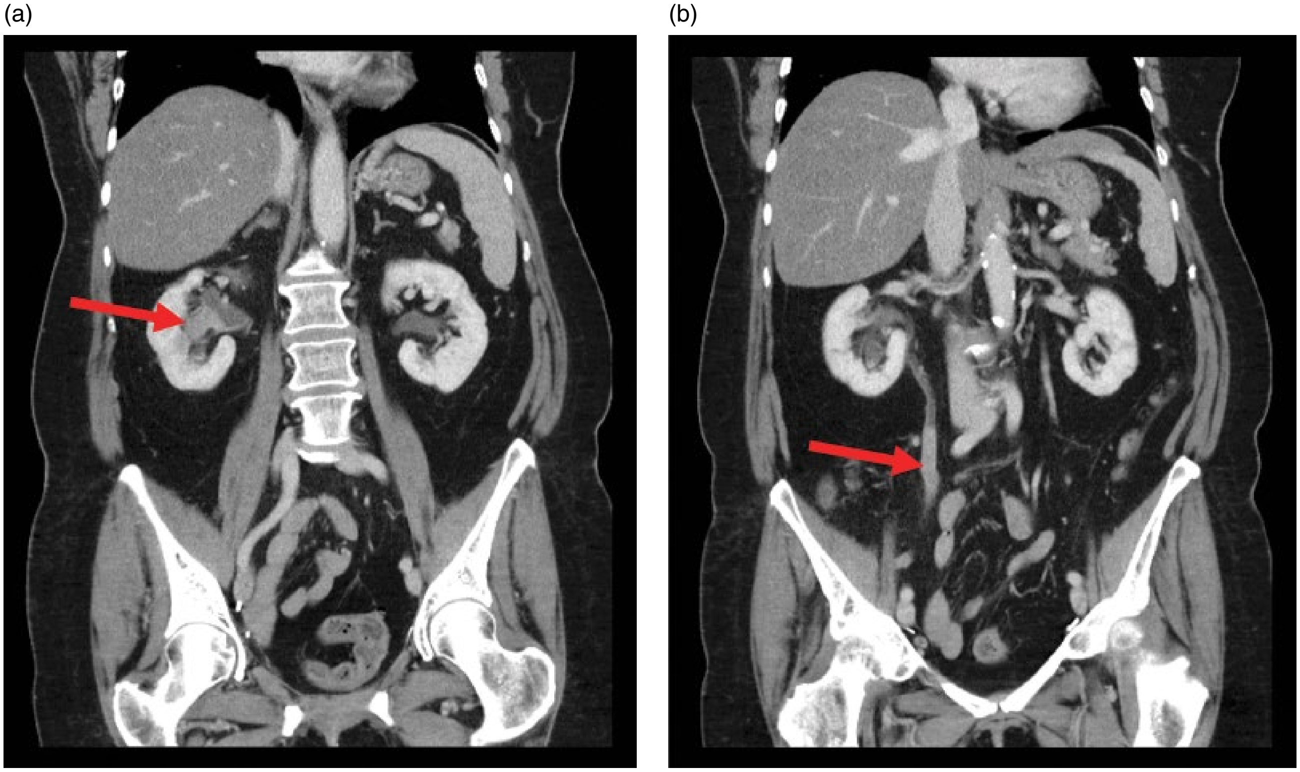

**Figure 123.28** Transitional cell carcinoma: coronal reformatted CT images. (a) There is a soft tissue mass occupying the inferior aspect of the right renal pelvis (arrow). (b) At a slightly more anterior level, a synchronous mass (arrow) is identified in the right mid ureter.

located than most RCCs. TCCs may contain stippled calcification and may be large and necrotic. They may distort the normal renal architecture. When RCC expands the kidney, the renal contour is usually preserved, in contradistinction to RCC. There may be obliteration of the renal sinus fat by tumor [88–98].

## Renal lymphoma

The kidney is one of the most common sites of extrarenal lymphoma. Nearly one-third of patients with non-Hodgkin's lymphoma will have renal involvement at autopsy. Indeed, lymphoma is the third most common metastasis to the kidney following carcinoma of the lung and breast. The antemortem diagnosis is only made in 0.5–8.3%. The cells in lymphoma infiltrate between and do not destroy normal renal cells and do not exhibit fibrosis so the effect on renal function is typically minimal [99–102].

Since the kidneys normally do not contain lymphoid tissue, most cases of renal lymphoma are due to direct extension or hematogenous metastases. Retroperitoneal lymphoma can invade the renal capsule directly or infiltrate the renal sinus fat encasing the ureter, renal pelvis, and renal vessels. Lymphoma can then extend into the renal parenchyma via the medullary pyramids. When lymphoma involves the renal parenchyma by direct extension or hematogenous spread, it initially involves the renal interstitium, using vessels, collecting ducts, and nephrons as scaffolding [99–102].

There are five major patterns of presentation of renal lymphoma radiologically:

- Multiple renal masses that are often hyperdense compared to normal renal tissue on noncontrast CT scans due to the hypercellularity of the tumor. On contrast-enhanced scans, these lesion present as multiple, bilateral, hypodense (Figure 123.30) intraparenchymal masses leading to a differential diagnosis of metastases, renal infarction, and renal infection.
- Diffuse renal infiltration causes nephromegaly but the renal arteries and veins remain patent despite encasement by tumor. On the early postcontrast images, the renal parenchyma appears remains relatively hypodense. On the nephrographic phase, relatively diminished enhancement is identified and there may be slight delay in excretion during the excretory

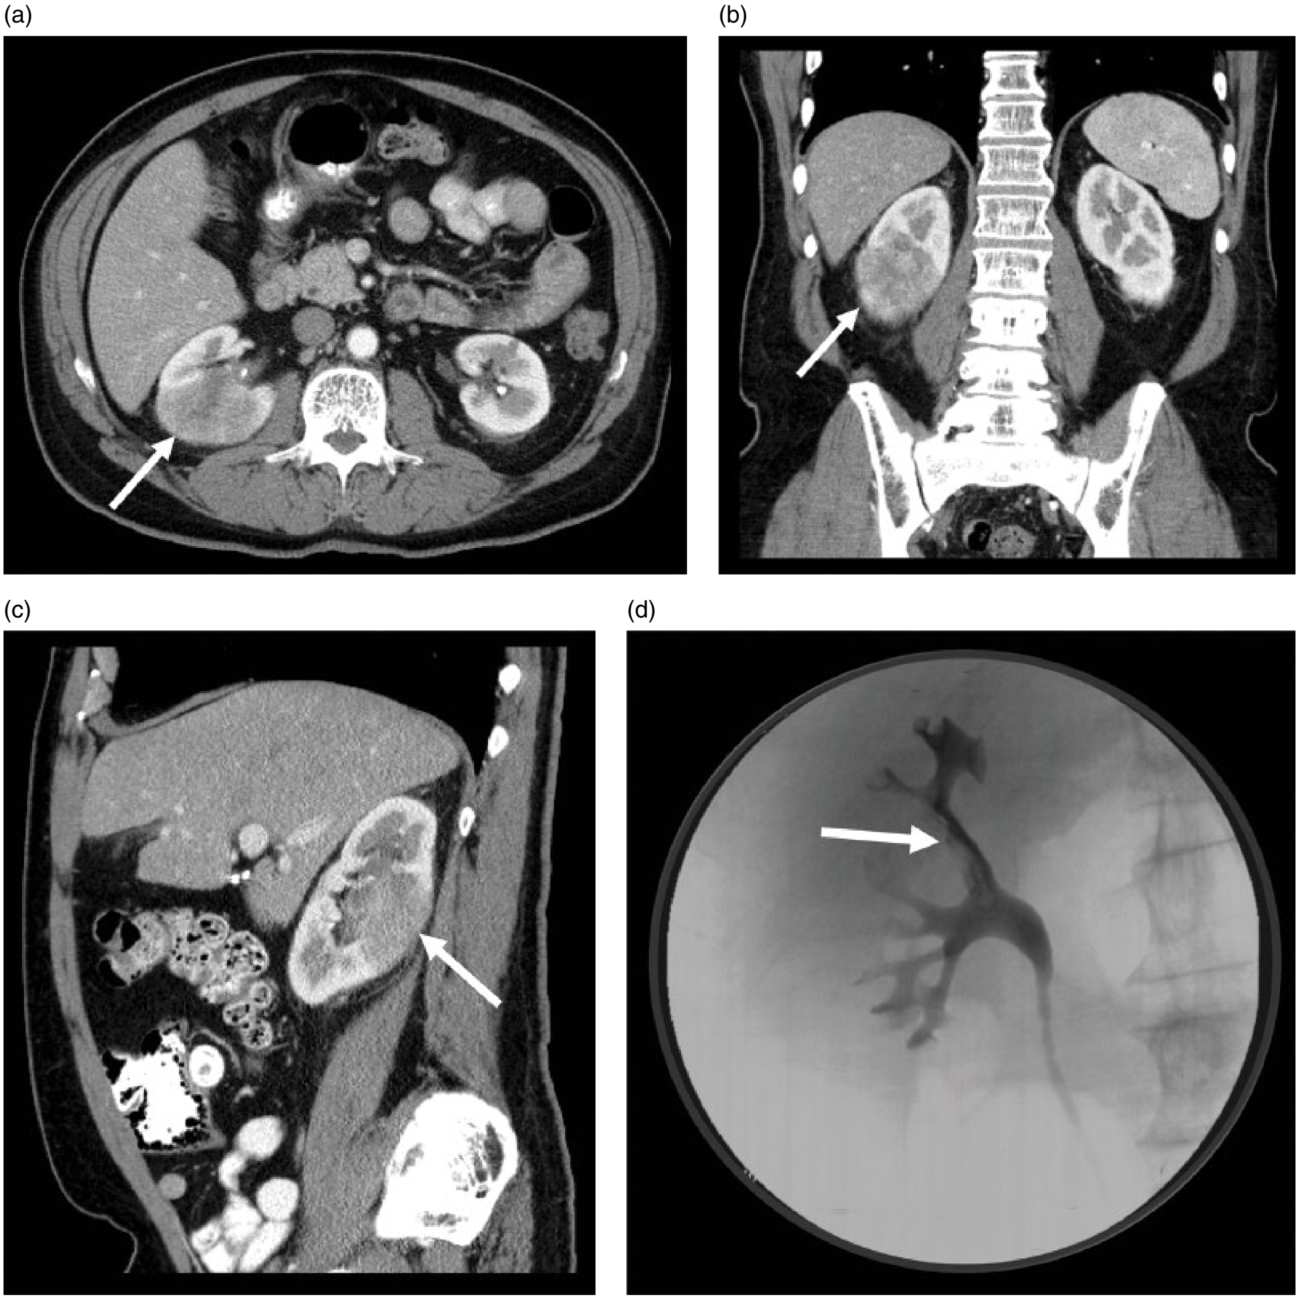

**Figure 123.29** Transitional cell carcinoma of the right kidney: imaging findings. Axial (a), coronal (b), and sagittal (c) CT images show a large hypodense mass (arrows) extending from the renal pelvis into the renal cortex. (d) Retrograde pyelogram image shows the mass (arrow) deforming the renal pelvis.

phase. The differential diagnosis of this presentation of renal lymphoma includes RCC, TCC, and diffuse renal infection.

- The renal capsule or renal sinus may also be directly invaded by contiguous involvement from retroperitoneal lymphoma. Retroperionteal adenopathy is present and this may cause hydronephrosis.
- More rarely, renal lymphoma presents as a solitary, hypoattenuating, intraparenchymal mass simulating a cortical tumor.
- Capsular (Figure 123.31) or perirenal involvement by lymphoma may occur with diffuse retroperitoneal adenopathy. The differential diagnosis in these cases includes perirenal hematoma and metastases [99–102].

## Renal metastases

Renal metastases are quite common in patients with extrarenal neoplasms, found in 7–13% of large autopsy series [17, 20]. The primary neoplasms that most commonly metastasize to the kidneys are: lung (Figure 123.32), breast, and gastrointestinal cancers [85]. These metastases usually have an indolent clinical behavior so were seldom discovered antemortem prior to the advent of cross-sectional imaging. By the time renal metastases are present, the patient usually has advanced disease. On rare occasions, a solitary renal metastasis may arise many years after the diagnosis of the primary neoplasm [1, 2].

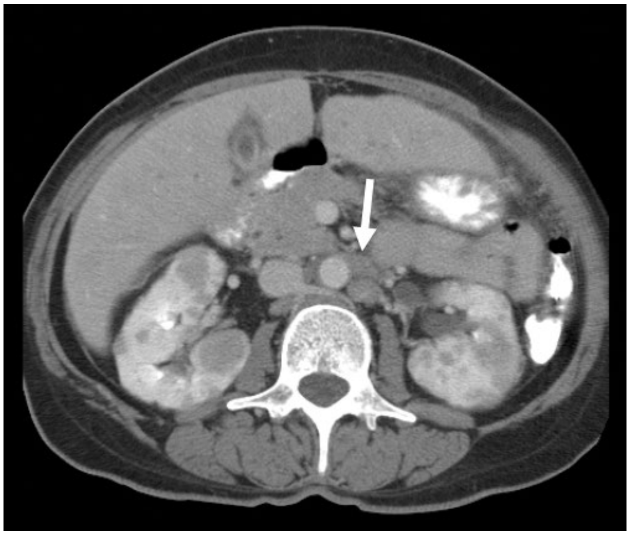

Figure 123.30 Renal lymphoma: CT findings. Multiple hypodense renal masses are present on this contrast-enhanced CT scan. Note the retroperitoneal adenopathy (arrow) as well.

Renal metastases, like lymphoma, can display an expansile or less commonly an infiltrative growth pattern. Most commonly, multiple bilateral masses are present. Solitary exophytic metastases are more common in patients with colon cancer, and perinephric tumor extension is identified in patients with melanoma [1, 2].

Patients who present with a solitary renal lesion and a known extrarenal primary tumor are a diagnostic challenge since the lesion may either be a metastasis or a synchronous renal neoplasm. The imaging findings in patients with renal metastases reflect the pathologic pattern of involvement and the nature of the primary tumor. A well-marginated hypovascular mass may be indistinguishable from a papillary RCC or lymphoma. Since infiltrative growth is atypically of renal cortical tumors, a solitary infiltrative renal mass in a patient with an extrarenal neoplasm most likely represents metastasis. Percutaneous biopsy will be needed for confirmation in these patients [25].

## Imaging and nephron-sparing surgery

Cross-sectional imaging plays a vital role in the selection and preoperative evaluation of patients for nephron-sparing surgery (Figure 123.33) and ablation [10–14]. MDCT nicely depicts the position of the kidney, anatomic variants, the depth of renal parenchymal invasion, the relationship of the tumor to the pelvicalyceal system,

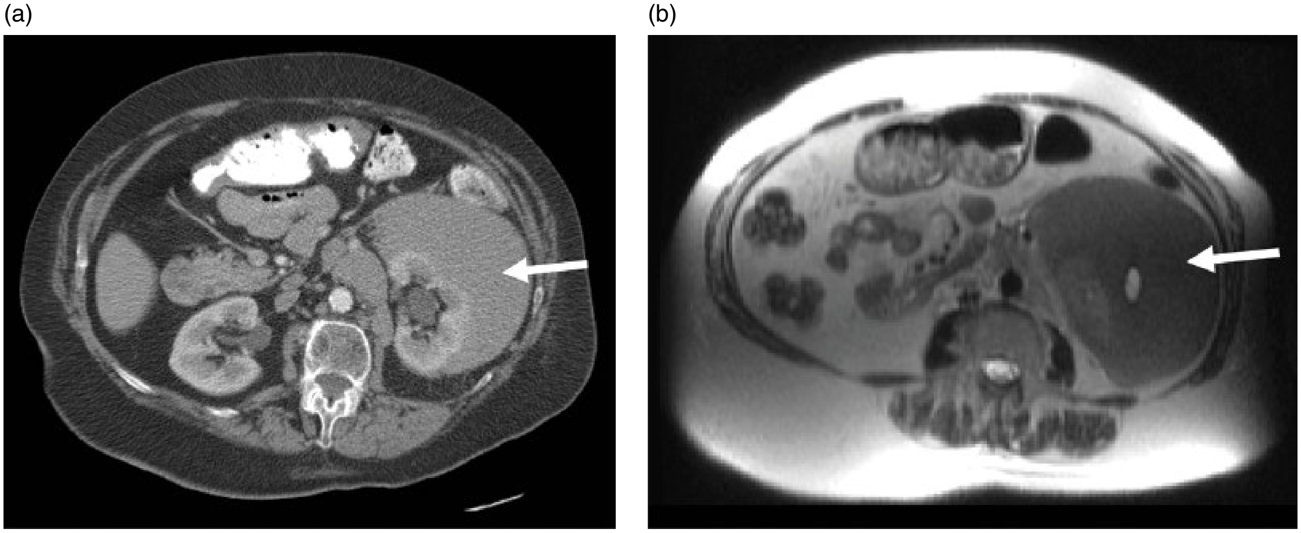

Figure 123.31 Perirenal lymphoma: imaging findings. Axial CT (a) and MR (b) images show a homogenous soft tissue mass (arrows) encasing the lateral aspect of the left kidney.

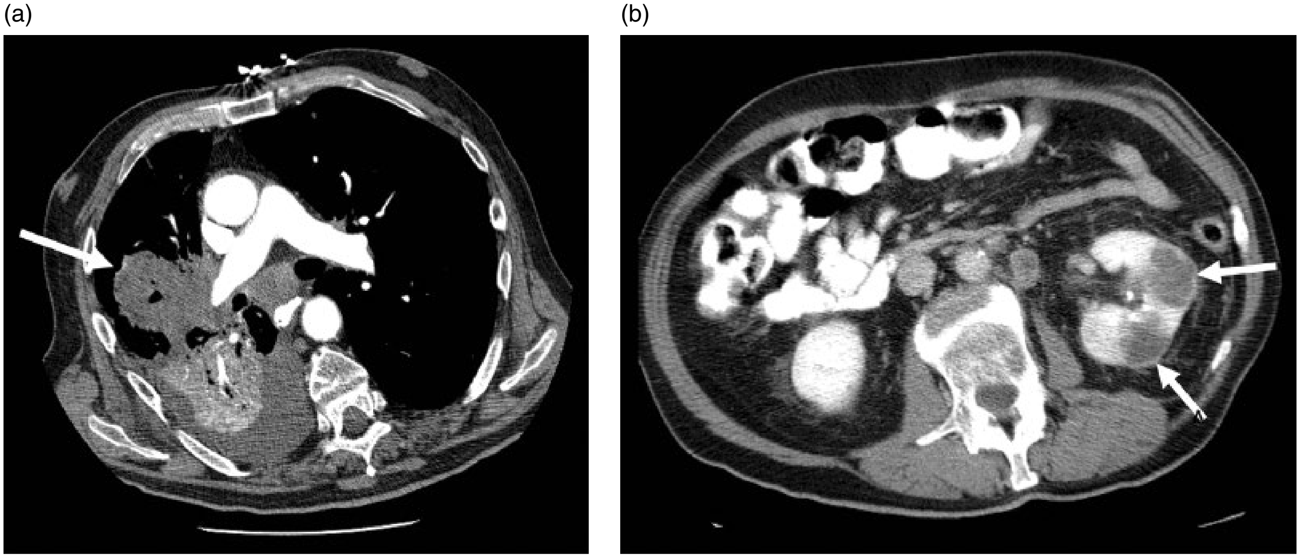

**Figure 123.32** Metastatic lung cancer to the kidneys. (a) Contrast-enhanced CT scan of the chest shows a large cancer of the right upper lobe (arrow) invading the right hilum with mediastinal adenopathy. (b) Scan at the level of the kidneys show two hypodense metastases (arrows).

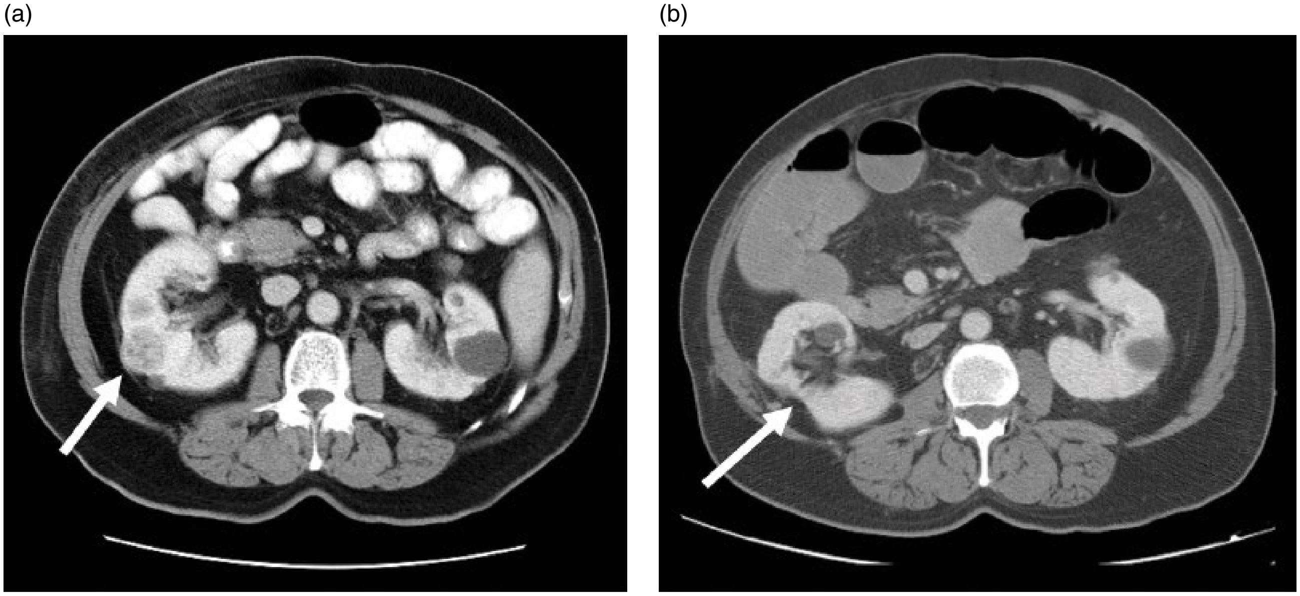

**Figure 123.33** Nephron-sparing surgery: CT features. (a) Small hypervascular cortical right renal cell carcinoma (arrow) prior to surgery. (b) Deformity of the lateral aspect of the right kidney (arrow) is evident postoperatively.

and detailed anatomic information concerning the renal arteries and veins.

Radiofrequency ablation (Figure 123.34) and cryoablation are now a commonly used alternative in the management of renal tumors. Tumors less than 4 cm in size are the best candidates for ablation. Renal tumors can be classified into three areas from an interventional standpoint: exophytic, parenchymal, or central. Exophytic lesions are the safest to treat. Central tumors are more challenging because of the proximity of the renal vessels, collecting system, and ureter. Tumor proximity to the vessels may lead to direct vascular injury or inadequate tumor margin treatment due to the heat sink effect. The ureter can also be injured, resulting in laceration or stricture [10–14]. Intraoperative ultrasound can show small tumors not detected at the time of surgery by conventional means.

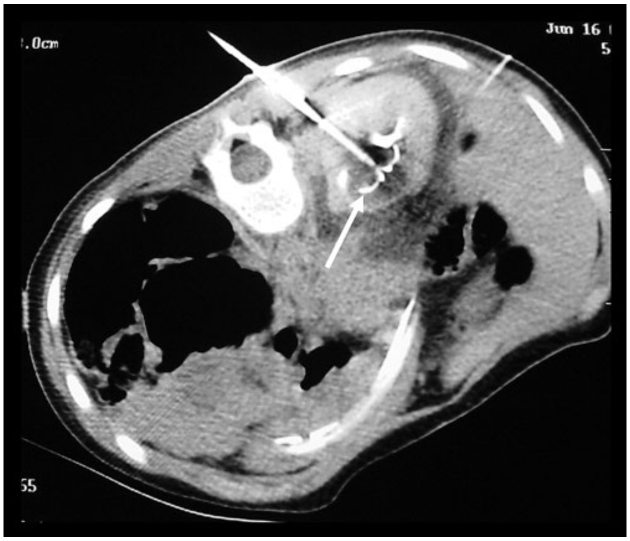

**Figure 123.34** Radiofrequency ablation probe (arrow) deployed in a renal neoplasm. Note the patient is in the prone oblique position.

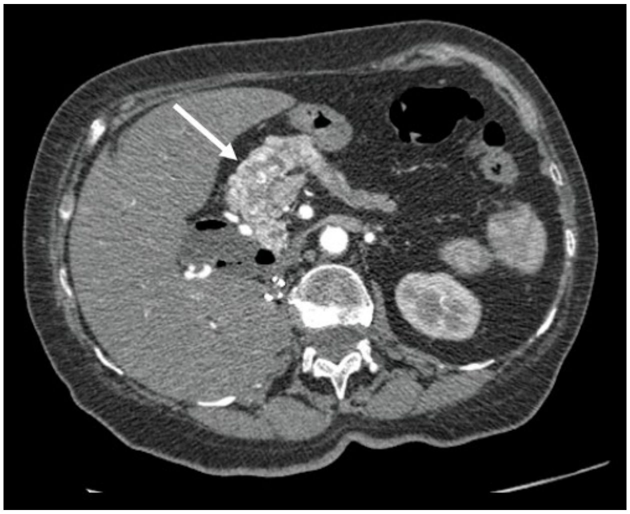

**Figure 123.35** Hypervascular metastasis from renal cell carcinoma to the pancreatic head. Contrast-enhanced CT shows a large, nonobstructing mass in the pancreatic head which developed 7 years following resection of a right-sided renal cell carcinoma.

## Recurrent cancer

Some 20–30% of patients with RCC that appears localized at the time of surgery relapse following radical nephrectomy. In the majority of cases, recurrence manifests as distant metastases rather than local disease, which occurs in less than 5% of cases. The stage of tumor at the time of presentation is the most important determinant of recurrent tumors. Other factors that increase the likelihood of recurrence include the presence of lymph node infiltration, high Furhman grade on histology, and the presence of sarcomatoid (spindle cell) architecture [103–105].

The median time from nephrectomy to relapse is 15–18 months and 85% occur within 3 years. Tumors that involve lymph nodes tend to recur early, whereas very late relapse can be seen with isolated metastasis to the lung, bone, pancreas, or skeletal muscle. Lung metastases account for 50–60% of distant relapses. These metastases may produce parenchymal consolidation or manifest as a hemorrhagic or lymph node-related mass [103, 104].

Recurrent metastases in the pancreas typically appear hypervascular on CT (Figure 123.35) and MRI, unlike the typically hypovascular masses seen in primary pancreatic adenocarcinoma. These metastases often develop quite late following resection of the primary neoplasm [103, 104].

Local recurrence is unusual and produces an enhancing mass at the site of nephrectomy. These tumors may infiltrate the adjacent quadratus lumborum and psoas muscles. The colon and small bowel can be directly invaded and when advanced can produce mesenteric nodal disease or peritoneal carinomatosis [103, 104].

MDCT is the imaging test of choice for the detection of local recurrent disease and distant metastases. If the patient has a contrast allergy, gadolinium-enhanced MRI of the abdomen and pelvis can be performed along with a noncontrast CT scan of the chest. Although not recommended in the initial evaluation of patients with renal malignancies, FDG-PET may have a role in the detection of recurrent distal metastases, especially if conventional studies are equivocal and in diffentiating recurrent tumor from postoperative fibrosis.

## Conclusions

State-of-the-art MDCT, ultrasound, MRI, PET-CT, and PET-MRI are leading to the earlier detection, better characterization, and improved staging of renal masses. As our increasing understanding of the diversity of renal neoplasia has been accompanied by innovative surgical and ablative techniques, cross-sectional imaging remains the linchpin in individualizing the treatment and follow-up of patients with renal masses. Biomedical imaging plays an increasingly important role in all phases of cancer management, including screening, diagnosis, biopsy guidance, staging, prognostic assessment, selection of a treatment plan, prediction and monitoring of treatment response, and assessment for recurrent disease.

## Introduction

Biopsy of renal tumors (BRT) was not accepted by urologists as a standard diagnostic method until recently [1–3]. Classically, indications for BRT extended to cases where a reasonable doubt existed on the presence of a renal cell carcinoma (RCC) and a differential diagnosis needed to be ruled out (e.g. metastases of other primary cancers, lymphoma, retroperitoneal masses of unknown diagnostic, suspicion of infectious process) and more recently to determine RCC subtype in metastatic cases with the aim of driving the choice of systemic therapy.

Surveys among urologists showed that the majority did not perform BRT, even in the presence of indeterminate lesions [4, 5], Major reason for abstention were the presence of false negative results or low predictive value and the uncertain value of biopsy in directing or changing management. Although the post-test probability of a diagnosis of RCC in cases with a negative renal mass biopsy was estimated at 18%, recent literature shows that a second biopsy in case of a nondiagnostic initial biopsy shows cancer in 75–80% of cases [6–8].

However, in a rapidly changing scenario where presentation of RCC is shifting to the early stages, the incidence of radiological small renal mass (SRM) has increased [9], the knowledge that up to 25% of those SRMs are benign, and the broadening therapeutic options or observation options (e.g. ablation and active surveillance), preoperative histological filiation of a renal mass is increasingly recommended in the most prominent guidelines [2, 3, 10].

Currently, up to 70% of kidney tumors are accidentally discovered before symptoms arise [11, 12]. The mean size of surgically treated tumors has decreased in the last two decades [13–15] and the absolute number of SRMs (≤4 cm) diagnosed has increased. Pathologic assessment of SRMs has evolved and the classical cut-off of 3 cm to distinguish a renal carcinoma from a benign adenoma is no longer valid. In addition to the established relationship between tumor size, RCC subtype, and grade, the increasing prognostic impact of grade is being considered, and new subtypes and RCC-associated entities are being recognized [16]. Conversely, evolving immunohistochemistry (IHC) techniques and molecular and genetic markers are emerging as promising diagnostic and prognostic tools to be applied to renal mass biopsy in the future [17–19].

Besides the fact that recent systematic reviews show that BRT is highly accurate when a diagnostic sample is obtained [8, 20], the introduction in the clinical practice of angiogenesis inhibitors and more recently the novel immunotherapy based on checkpoint block point out the capital of determining RCC subtype to apply for the most adequate treatment strategies [21, 22].

When cross-sectional imaging is reviewed, the problem is not the differential diagnosis in the case of large renal masses but the differentiation and filiation of SRMs [23, 24]. Contemporary surgical series show a benign tumor incidence of 20–30% among SRMs and this incidence is inversely proportional to size [23, 24]. Although bias cannot cannot be ruled out in surgical series, because of the inclusion of different Bosniak categories, cysts, or inaccurate radiological assessment, the percentage of benign masses in this size range is clearly too high to justify an intervention without histologic confirmation of malignancy or a reasonable doubt that the mass is benign.

Among SRMs, subtype aggressiveness and grade increase its size and although the 2009 TNM classification still establishes a stage size cut-off of 4 cm for clinical or pathological definition of T1a, there is some evidence that a definitive cut-off for aggressiveness can be established at the 3 cm diameter [25, 26].

Partial nephrectomy or enucleation, the standard of treatment for SRMs, which is historically underused [9, 27],

*Smith's Textbook of Endourology*, Fourth Edition. Edited by Arthur D. Smith, Glenn M. Preminger, Louis R. Kavoussi, and Gopal H. Badlani.

Companion website: www.wiley.com/go/smith/textbookofendourology

has increased in recent years, especially since the development of robotic assistance [28], and this has led to overtreatment of benign SRMs and small RCCs [29, 30]. At the other end of the management spectrum, a biopsy provides information for a decision on ablation or surveillance of an SRMs and further follow-up vigilance.

## Biopsy nomenclature

The nomenclature used for the results of a BRT deserves special consideration to avoid misdiagnostic and to properly frame the diagnostic performance of the test.

In basic terms, when a renal tumor is evaluated, a biopsy can deliver one of two results: diagnostic (benign or malignant) or nondiagnostic (Figure 124.1). When the biopsy is diagnostic, other characteristics, such as histopathologic type and subtype and grade, can also be assessed.

Pathological interpretation of "nondiagnostic samples" includes insufficient material, inconclusive results, and normal renal parenchyma, as well as inflammation, necrosis, or blood only [8, 10, 20].

There are various reasons for a nondiagnostic biopsy (Table 124.1). Conceptually a failed biopsy means that no tumor tissue is found in the biopsy specimen sample, although other types of tissue might be present in the sample. The reason for a failed biopsy could be a technical failure of the puncture method (e.g. misfire or malfunctioning of the biopsy gun) or an incorrect sampling. Incorrect sampling is sometimes unavoidable due to the nature of the renal tumors: these may contain necrotic and fibrotic tissue, or be mixed in nature with solid and cystic components. The presence of normal renal tissue also implies that the sampling is incorrect as very few renal masses are composed of normal renal tissue. The presence of fibrotic, inflammatory, fatty, or necrotic tissue in the specimen means that a diagnosis cannot be made from it.

In indeterminate (or inconclusive) biopsies, tumor tissue is present in the biopsy specimen but it is impossible to determine the biology of the cells. In this case, IHC or genetic techniques may be of help if enough tissue is available [17, 18].

Definitions in the literature are elusive and consequently there is overlap between failed, incorrect sampling, and indeterminate biopsies.

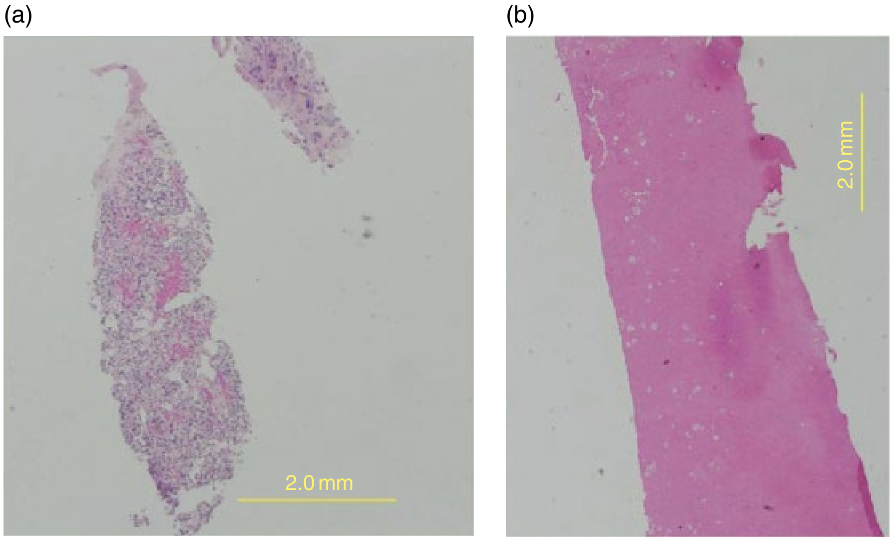

**Figure 124.1** (a) Diagnostic and (b) nondiagnostic (fibrin) core biopsy of a renal tumor.

**Table 124.1** Nomenclature of the nondiagnostic biopsies based on the sample findings, and reasons leading to a nondiagnostic result.

| Nomenclature | Tissue in the sample | Reasons |
|---|---|---|
| Failed biopsy | Absence of tumor cells (other types of tissue may be present) | Technical failure (e.g. misfiring)<br>Erroneous sampling (e.g. normal kidney, fibrosis, fat, inflammation, necrosis, blood) |
| Indeterminate (inconclusive) biopsy | Impossibility to differentiate benign from malignant cells | Insufficient cells<br>Morphologic overlap<br>Cellular heterogeneity |

Diagnostic yield is the rate or percentage of all biopsies with a definitive diagnosis. Diagnostic biopsies can also give false results, both positive and negative, and the sum of these is the rate of inaccurate biopsies. Accuracy is then calculated from the total number of diagnostic biopsies.

In addition to technical failures and indeterminate biopsies, benign nontumoral conditions (e.g. normal renal parenchyma, fibrosis, granulomatous tissue) found in the biopsy specimen are classed as diagnostic by some and nondiagnostic by others. Variations in results are conditioned by the lack of standardization of the taxonomy but also by the well-proven interobserver variability among pathologists. Interobserver variability may be responsible for up to 11% difference in the rate of nondiagnostic biopsy for both core biopsy (CB) and fine needle aspiration (FNA) [6, 31–33].

## Renal biopsy technique

Two aspects should be considered when assessing the technique of percutaneous renal biopsy: the type of image guidance and the type of biopsy performed (CB or cytologic aspiration (FNA)).

### Image guidance

Currently, most renal mass biopsies are performed percutaneously and supported by image guidance using computed tomography (CT) or ultrasound. Biopsies are normally performed under local anesthesia in an outpatient setting. When performing biopsies during surgery or *ex vivo*, direct vision can be used. Compared with *ex vivo* renal mass biopsies, recent studies with imaging-guided percutaneous renal mass biopsies have shown better outcomes in terms of failed or indeterminate biopsies [8, 10, 20, 34]. The outcomes of biopsies performed using ultrasound, CT or magnetic resonance imaging (MRI) are similar and therefore the choice between the radiologic modalities should be made on grounds of availability, location of the tumors, and ultrasonographic appearance [10, 35–38]. MRI-guided biopsy is not widespread as it entails the use of more costly, nonferromagnetic needles [35].

#### Ultrasound

Ultrasound guidance has several advantages over CT-guided renal mass biopsy. It is generally available and less costly, results in less radiation, can be performed by the urologists during the initial workup, provides real-time and multiplanar imaging, and the device is portable and user friendly [39]. However, not all lesions are visualized on ultrasound and anatomy may limit access to the tumors (e.g. rib shadow and gas obscuring visibility). In addition, performing ultrasound-guided renal biopsies requires a significant learning curve. Visualization of the needle tip on ultrasound can be improved by several methods [40]. Biopsies can be performed either using a guide or "freehand."

#### Computed tomography (Figure 124.2)

Among the advantages of CT guidance are the fact that most renal masses can be identified after contrast injection and that the puncture of intratumoral features that may be prone to a nondiagnostic results (e.g. hemorrhagic zones that can result in necrosis or cystic component) can be avoided, optimizing the results of the biopsy. Adjacent organs can also be optimally identified and the technique is easier to master. These advantages are even more significant in obese patients. However, real-time CT imaging is potentially hazardous for the investigator and patient due to radiation exposure and iodine injection is contraindicated in patients with allergy or severe chronic kidney disease. It is possible, due to manipulation of the needle, that the biopsy is performed outside the selected target, leading to a false negative result.

### Type of biopsy

Two types of biopsy can be performed under radiological guidance: fine needle aspiration (FNA), which provides cells for cytological analysis, and core biopsy (CB), which provides a cylinder of tissue of variable dimension depending on the caliber of the needle used.

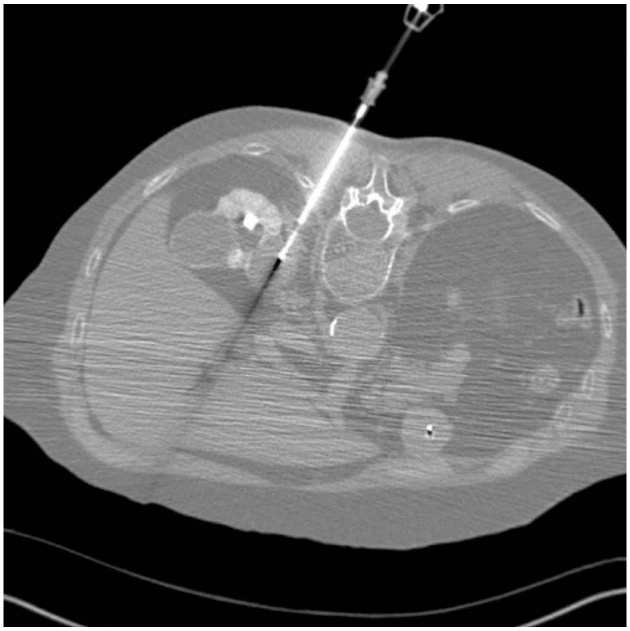

**Figure 124.2** CT-guided biopsy of a renal mass in the right kidney (patient in the prone position).

### Fine needle aspiration

FNA or cytologic aspiration is performed under image guidance. When the patient is properly positioned, the most suitable needle path is chosen. A guiding cannula is advanced onto the tumor surface and the needle is passed through the cannula into the tumor, trying to avoid possible necrotic areas. The cannula is used to avoid direct contact between the tumor and surrounding retroperitoneal tissue, decreasing the risk of tract seeding [40, 41]. The needle is then moved back and forth within the tumor to collect the cells. Traditionally, negative pressure with a syringe is applied on the needle in order to collect more cells. Another method that does not use negative pressure is Zajelda's fine needle capillary technique. This tends to reduce the amount of blood in the sample, but may result in fewer cellular smears [35]. If a CB and FNA are to be performed in the same session, the FNA should be performed first, to reduce the amount of blood in the cytologic specimen [35]. The aspirate is placed on slides and smeared directly. An onsite cytotechnologist can immediately determine the quality of the specimen, which should increase the rate of diagnostic FNAs and subsequent CBs since correct needle placement is ensured [35].

Cytologic examination can provide cytologic detail that is sometimes superior to the features in CBs (Figure 124.3). FNA samples can be used to prepare cell blocks which are helpful to identify specific histoarchitectural features and to perform IHC studies. A recent study has shown excellent results with an improved agar microscopy, which entails processing the aspirate of FNA by centrifuging it in agar. This technique results in concentrated cell blocks composed of fragments and loose cells that are suitable for slicing and subsequent histologic interpretation with IHC [42]. Additional

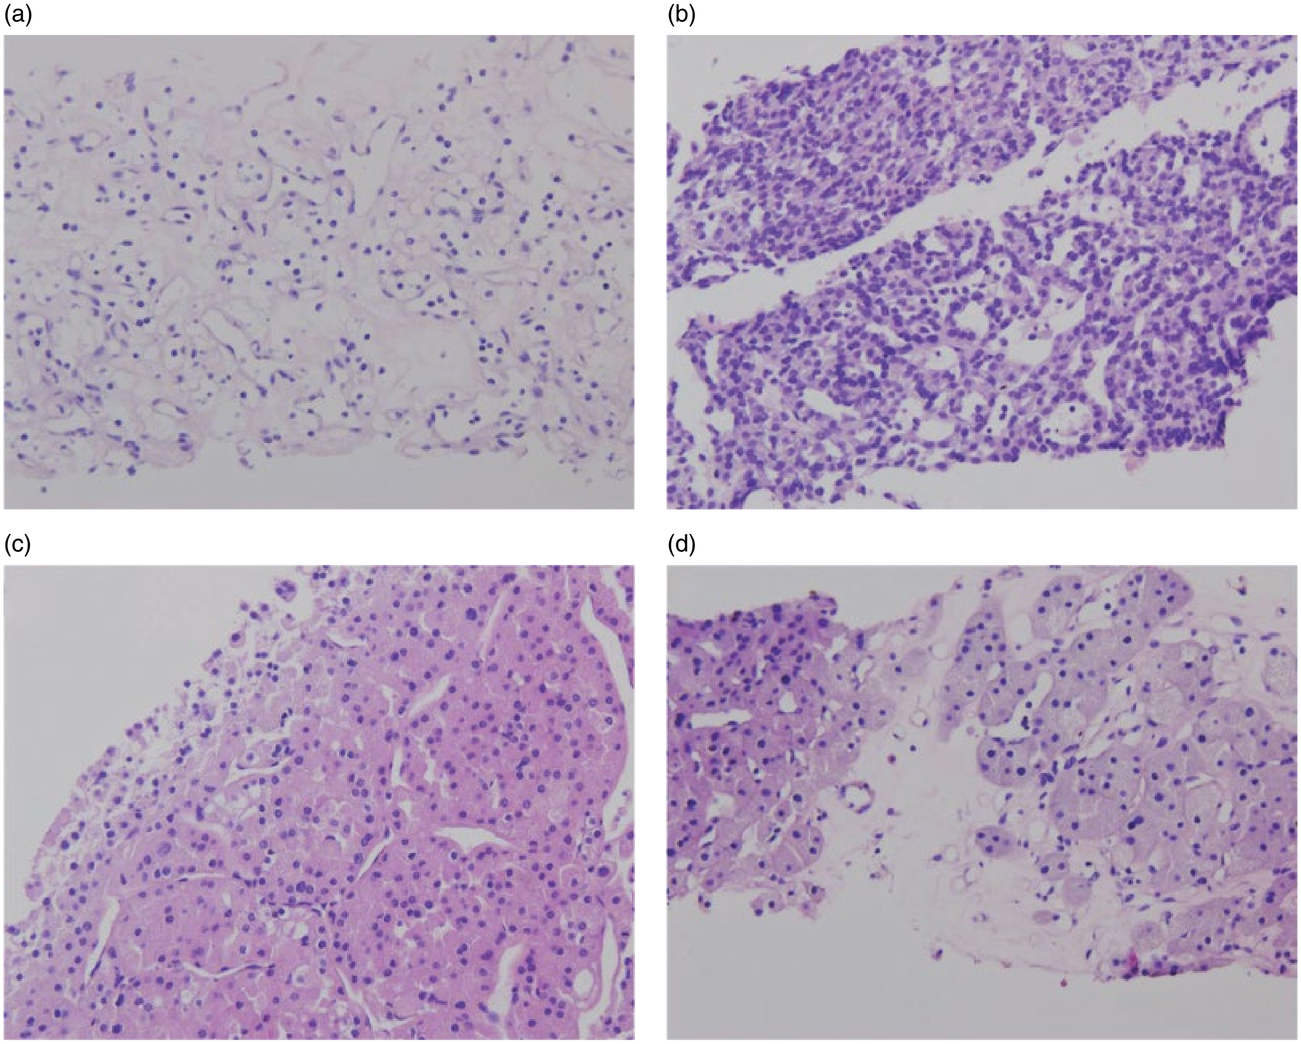

**Figure 124.3** Histopathologic core biopsy samples (H&E staining) of different subtypes of renal cell carcinoma and oncocytoma: (a) clear cell renal cell carcinoma; (b) papillary renal cell carcinoma; (c) chromophobe renal cell carcinoma; (d) oncocytoma.

testing, such as flow cytometry, fluorescent *in situ* hybridization (FISH), apoptosis assays, and picrosius red F3BA staining, are also possible with FNA [35].

### Core biopsy

CB is performed with a hollow needle, allowing it to remove small but solid samples of tissue suitable for fixation and histologic examination (Figure 124.4). The needle has a cutting edge that allows tissue samples larger than 1 cm in length to be removed. Thicker needles than for FNAs are used (17G or 18G). The risk of complications does not increase with the use of these needles [17, 18, 37, 43–50]. Usually, 18G or 17G needles are used with an automatic biopsy gun to obtain tissue samples of 15–22 mm in length. The quality of the core should be checked at the time of the biopsy, in order to repeat it if there are doubts about its quality [51].

## Technical considerations

Some technical considerations on FNA and CB may improve the quality of the sampling and maximize the results.

The choice of radiologic imaging depends on tumor location, size, access feasibility, visibility and individual preference. Imaging is used to avoid areas suggestive of pathologic necrosis or cystic areas. The same considerations apply to the choice of biopsy type (FNA or CB). In general, higher accuracy has been shown for CB, although experienced groups achieve the same results with FNA [52]. The combination of both biopsy techniques during the same procedure increases the diagnostic yield [53].

Larger needles have shown better results in terms of sample quality, and there is no increased risk for complications when comparing 18G to 22G needles [35, 37, 42,

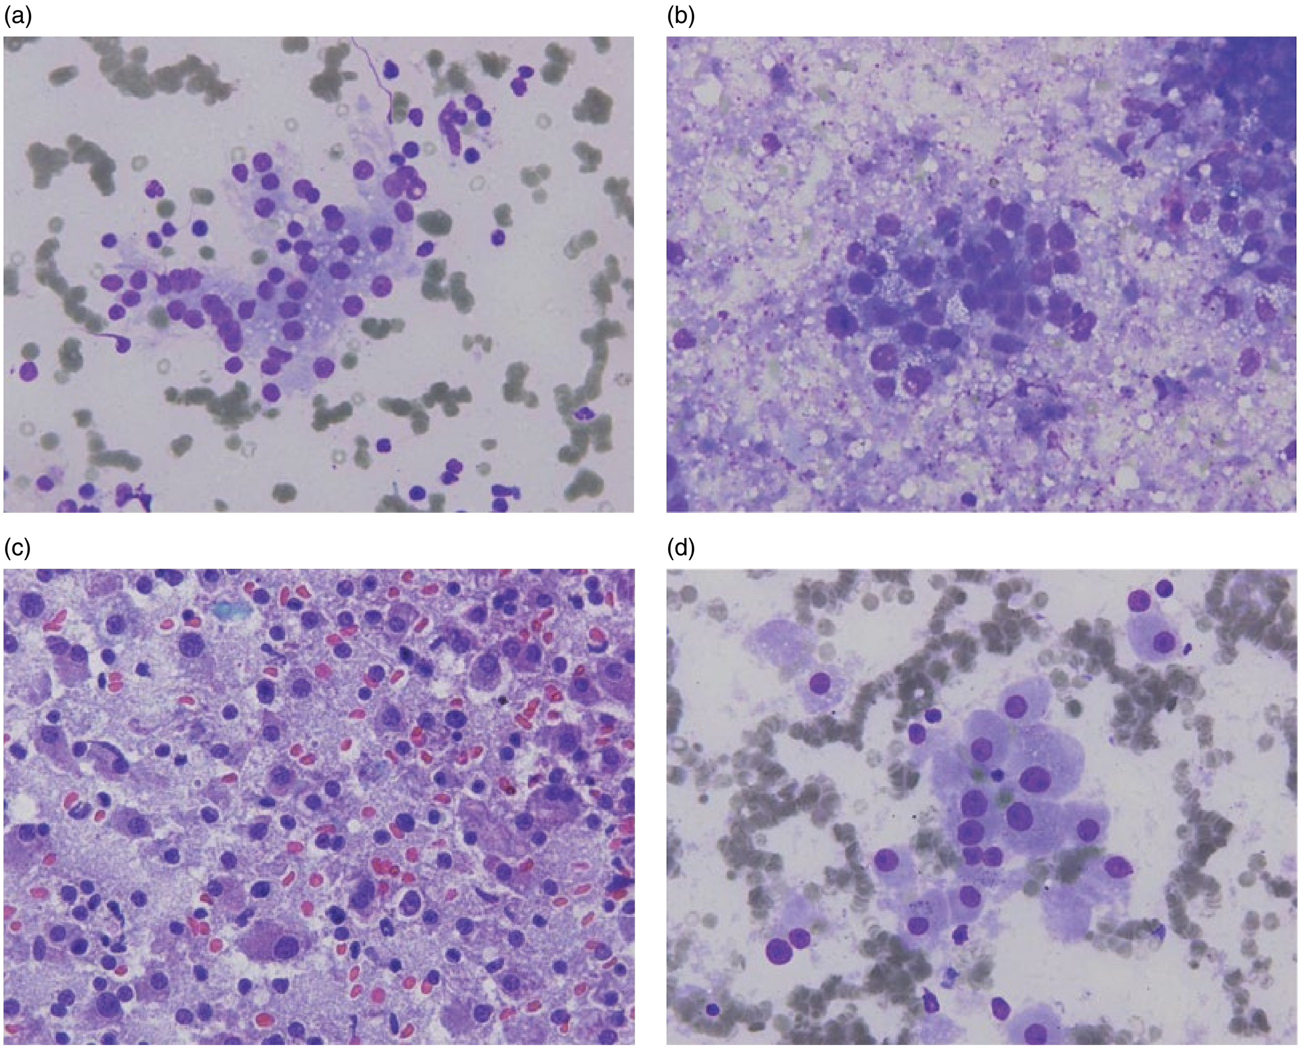

**Figure 124.4** Fine needle aspiration biopsy samples (Giemsa staining) of different subtypes of renal cell carcinoma and oncocytoma: (a) clear cell renal cell carcinoma; (b) papillary renal cell carcinoma; (c) chromophobe renal cell carcinoma; (d) oncocytoma.

47–50] (Figure 124.5). The *ex vivo* performance of three distinct needle calibers (14G, 18G, and 20G) has been compared in a blinded study [54]. One core biopsy (H&E and standard IHC panel) was obtained with each needle from 31 tumors. All biopsies performed with the 14G and 18G needles provided sufficient tissue for diagnosis, whereas the technical failure rate for the 20G needle was 14%. Sensitivity to distinguish between benign and malignant tumor was high for the three needle calibers, but specificity was lower for the 20G needle. Histologic accuracy was 92%, 97%, and 81% for 14G, 18G, and 20G needles, respectively. Grade accuracy was consistently low for the three needles (40–56%) and it was concluded that one core biopsy with an 18G needle offers the highest accuracy in histology diagnosis [54]. The widespread use of thick needles could be partly responsible for the current increasing accuracy and decreasing failure rate of the biopsies [34].

Different type of needles are available to perform a CB. Automatic Tru-Cut needles are easier to manage than the original manual Tru-Cut needles.

Tumor size influences the results of the biopsy. Since larger tumors more frequently have central necrosis, it is recommended to perform a peripheral and a central biopsy in tumors smaller than 4 cm and two peripheral biopsies for tumors larger than 4 cm [55]. The literature, including a recent consensus document, advises at least two CBs to be taken when a BRT is envisaged [10, 34, 35, 44]. For FNA, as many passes as necessary should be performed to ensure a diagnostic smear. Ideally, the cytologist should prepare the smear directly "on site" after puncturing and examine it to ensure the presence of cells and to give the opportunity to repeat the cytologic aspiration if necessary.

In both CB and FNA it is recommended to use a cannula that is wider than the biopsy needle to be used.

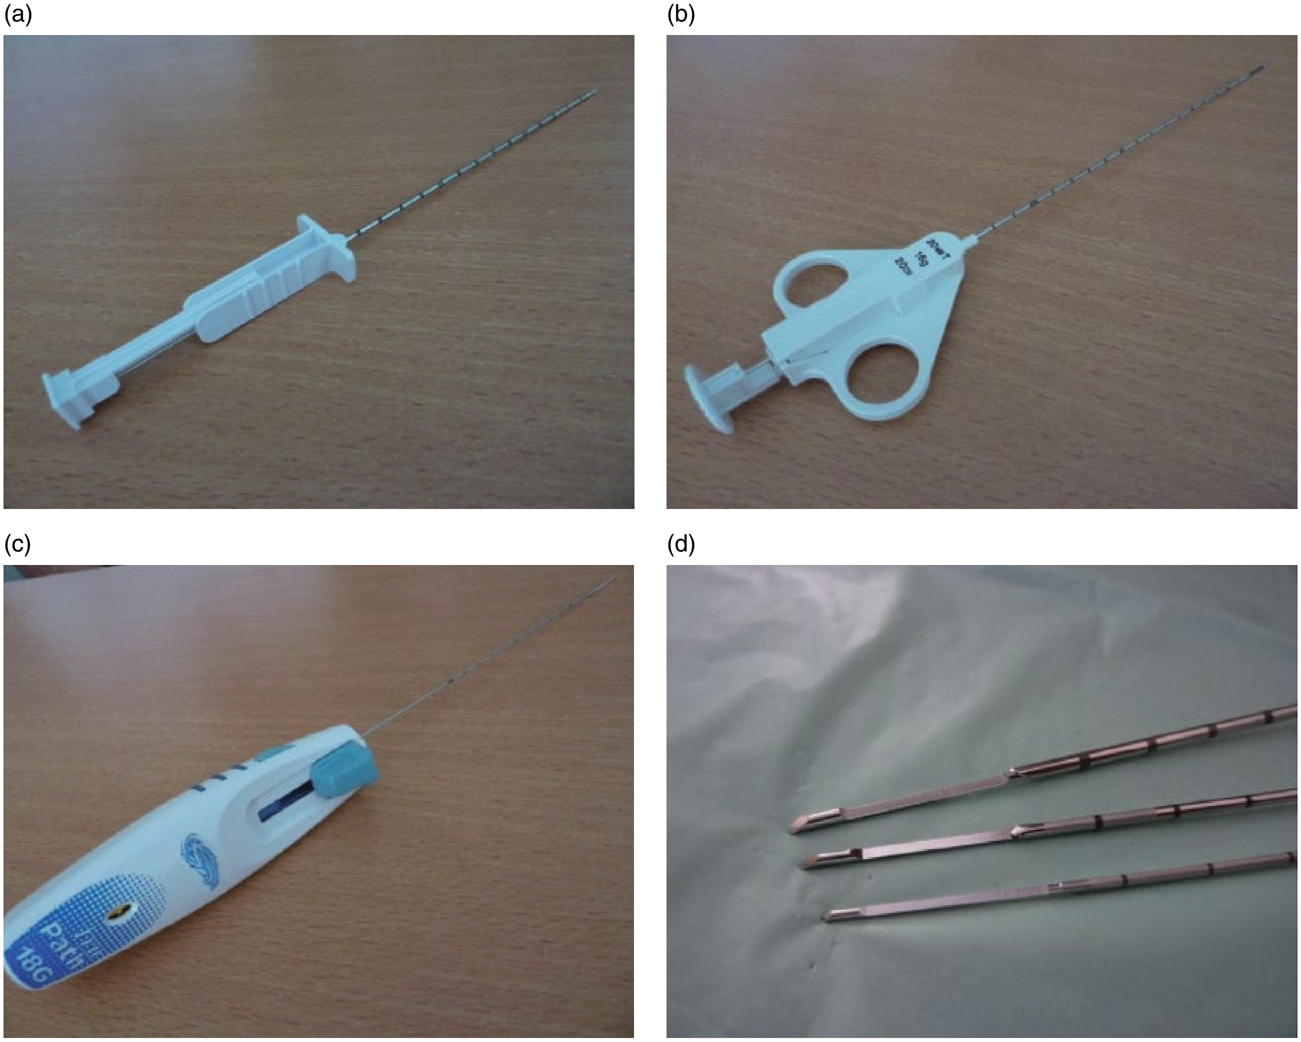

**Figure 124.5** Core biopsy needles: (a) manual 14G needle; (b) semi-automatic 16G needle; (c) fully automatic 18G needle. (d) Needle tips of the 14G, 16G, and 18G biopsy needles (top to bottom). All cores obtained are between 18 and 20 mm in length.

This cannula is advanced under imaging onto the surface of the tumor and remains stable during the whole procedure. The biopsy needle is advanced through the cannula, which allows a number of passes or biopsies to be performed without the risk of contamination or seeding, and avoids manipulation of the chosen tract.

Although bleeding complications are rare (see below), coagulation abnormalities should be corrected prior to biopsy, anticoagulants should be stopped when possible, and some hours of rest are recommended after biopsy.

## Complications

Complications of renal biopsy are rare. Potential complications of percutaneous renal biopsies are bleeding, tumor seeding along the needle tract, arteriovenous fistula, infection, and pneumothorax.

Overall, complications after BRT occur in 8.1% (2.7–11.1%) of patients [8, 20, 34, 51]. Most complications are Clavien grade I, and only few of grade II or more are described. Mortality has not been described in the recent literature [8, 20, 34]. The most frequent complication, perirenal hematoma, occurs in 4.3–4.9% of cases but less than 1% of the patients require blood transfusion. Self-limiting gross hematuria may present in up to 3% of patients and lumber pain in 1–3% of cases. The incidence of pneumothorax or need for embolization (Clavien III) is lower than 1% [8, 20, 34, 56, 57]. Reports on a possible correlation between needle size and rate of complications are controversial [50, 58, 59]. A correlation might be found when 15G needles are compared with 21G needles; however, no significant difference in complication rate has been found between 18G and 21G needles [59].

The most feared complication of renal biopsies is tumor seeding. However, in all recent series of BRT (from 1994 onwards) no cases of tract seeding have been reported in RCC. A possible explanation is the widespread use of a guiding cannula for BRT [35, 60]. Because tract seeding has been described in urothelial carcinomas, when urothelial cell carcinoma is suspected, a percutaneous biopsy for diagnostic purposes is not recommended [60, 61].

Other complications occur very rarely. Arteriovenous fistula should be ruled out in cases of persistent bleeding [62]. When the renal biopsy is performed through a posterior approach, pneumothorax has been reported in 14–29% of cases, although most of them not clinically significant [57, 61]. To further minimize the risk of a pneumothorax, the puncture should be performed in expiration and the needle positioned subcostally. Some upper pole tumors can be punctured using the paravertebral approach, which involves the injection of saline in the paravertebral space to displace the pleura laterally [63].

There is no evidence that a renal mass biopsy can complicate a subsequent partial or radical nephrectomy [50, 64, 65], although in case of hemorrhagic complications it seems reasonable to delay surgery, when possible, for some weeks.

## Results

A number of studies have assessed the diagnostic accuracy of renal mass biopsy, most of them retrospective. Early studies focused on cytologic aspiration with Chiba needles, but the incorporation of automatic fine CB needles minimized trauma and allowed core samples to be obtained that were easier to analyze.

The accuracy of a diagnostic test is measured by sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV). The results of a diagnostic test (index test) should be compared with the standard results (standard for comparison). In BRT, the ideal for comparison is the histopathological examination of the surgical specimen where histology, RCC subtype, and grade can be accurately characterized. Unfortunately, the literature shows that only a few series provide cohorts with a complete comparison between BRT histology and surgical specimen [8, 20, 34]. Comparison in 100% of the cases between BRT and surgical specimen is performed in a few series. This missed comparison is most prominent when a benign diagnostic is established by renal mass biopsy [8].

### *Ex vivo* biopsy

Several studies have evaluated the accuracy of *ex vivo* (in-bench) biopsy for the diagnosis of renal tumors [6, 17, 18, 32, 33, 54, 55, 66, 67]. The accuracy of biopsy taken directly from a surgical excision specimen (nephrectomy or partial nephrectomy) under direct vision was compared to the definitive pathological diagnosis of the surgical specimen in 100% of the cases. In most of the studies pathologists evaluating the biopsy were blinded to the definitive histopathological results.

*Ex vivo* CBs were sufficiently accurate to differentiate between a malignant and a benign renal mass (Table 124.2). Overall accuracy varied from 72% to 90%, and was not lower for FNAs [32]. The rate of nondiagnostic biopsies varied from 2% to 20% with a trend to be higher than in the modern percutaneous biopsy studies [34]. Using the same nomenclature as in the article by Lane et al. [34], Kummerlin et al. described a rate of failed biopsies (called “nondiagnostic”) between 8% and 16% for the five pathologists involved in the study, and a rate of indeterminate biopsies (called “nonconclusive”) between 0% and 8% [31]. This fact may be explained by the lack of visualization of the entire tumor, as can occur during imaging or in the

absence of needle stabilization during percutaneous puncture. Subtype differentiation between oncocytoma and chromophobe RCC remains problematic (see Figures 124.3 and 124.4). Kummerlin et al. found a good overall accuracy for *ex vivo* FNA in differentiating between malignant and benign masses [29, 32]. However, again there was a substantial interobserver variation regarding the subtype differentiation, other than for clear cell RCC.

When interpreting the results of in-bench biopsy studies, it has to be taken into account that this *ex vivo* setting is only partially comparable to clinical practice, where percutaneous biopsies will be the standard.

## Percutaneous biopsy

In 2008 Lane et al. published an extensive review on the subject [34]. They divided the studies chronologically between those conducted before 2001 and those from 2001 onwards. Before 2001, 27 studies were considered, in two of which "*ex vivo*" tumor biopsy was performed. After 2001, seven clinical studies and three *ex vivo* studies were considered. Overall diagnostic accuracy of 88.9% was reported for the earlier period (including *ex vivo* biopsies). When *ex vivo* biopsies were excluded, clinical accuracy increased to 96% in the later period. These figures suggest an improving trend in the diagnostic performance of the biopsy. Furthermore, false negative and false positive rates both decreased between periods.

The accuracy of the biopsy was calculated based on the number of successful biopsies. Biopsy failures – defined as "the inability to obtain an amount of tissue sufficient for diagnosis" – were excluded from the accuracy assessment. In clinical practice, the physician should be aware that diagnostic yield is different from accuracy, as the biopsy failures still accounted for 9% and 5.2%, respectively, for the two periods. Indeterminate biopsies were included in the accuracy assessment in the review. However, an indeterminate biopsy is in fact a nondiagnostic biopsy. The sum of technical failures plus indeterminate biopsies ("no definitive diagnosis possible using the available techniques") was 19% and 10%, respectively, in the two periods [34].

Most recently, two systematic reviews have confirmed the results of Lane et al. [8, 20]. Although the number and chronology of the included articles differs, both reviews aimed to quantify accuracy and rate of adverse events. Accuracy of the biopsy was calculated in both reports excluding nondiagnostic biopsies. Essentially, the definition of nondiagnostic biopsy included any normal renal parenchyma, presence of blood, necrosis, inflammatory, fibrotic, or extrarenal tissue only and insufficient or nonadequate tissue for diagnostic.

The nondiagnostic rate in these two systematic reviews is reported as 8% and 14%, although it varies widely across studies from 0% to 26.6% for CB and from 0% to 36% for FNA [8, 20]. Sensitivity in distinguishing malignant from benign tumors is very high in both systematic reviews for CB (97.5% and 99%) and slightly lower for FNA (93.2%), and lower in cases of cystic masses (83.6%). Specificity was also very high in both reports (96.2% and 93.2% for CB) [8, 20]. However, NPV remains low when results are compared with the surgical standard (63.3%) [8].

These overall excellent results were reproduced when the analysis was performed exclusively in studies looking at SRMs [8, 20].

When considering these results, limitations common to the three reviews deserve mention [8, 20, 34]. First, the studies included in all these reviews compared the results of the BRT with several different standards. The index test varies from pathologic examination of the surgical specimen to radiologic follow-up in the case of non-extirpated tumors [7, 8, 20, 34]. For example, in the period before 2001, surgery, and consequently surgical specimen available for comparison, was noted in only 49.5% of the cases previously biopsied, excluding the *ex vivo* biopsy studies for which a surgical specimen was obviously available in all cases. The number of cases with surgical specimen available for comparison increased to 54% in the second study period [34] and is similar when RCC is diagnosed by BRT in the most recent reports [8]. The recent literature does not support the lack of radiologic growth as absence of malignancy [68, 69]. In short, old or new, the comparison of BRT histology to the pathology of the surgical specimen is available in less than half of the patients, with 100% of pathological specimens available in few series and thus the real PPV and NPV cannot be properly assessed.

Second, most of the series are retrospective and thus bias selection cannot be ruled out. Finally, heterogeneity among series in terms of selection criteria, technical issues (e.g. needle used, type of biopsy), and the different number of cases included precludes proof of sound statistical comparison.

All these reasons represent potential sources of bias in the interpretation of the analysis, and might lead to overestimation of the biopsy accuracy.

In an attempt to clarify the results, we further examined those series where pathologic confirmation was obtained in the form of a surgical specimen in 100% of cases, whether *ex vivo* or in the clinical setting, including with a preoperative percutaneous biopsy. Results of SRM biopsy are also considered separately, because it may not be possible to extrapolate results from general series to these masses.

## Percutaneous biopsy compared with 100% surgical specimens

The number of studies on the accuracy of percutaneous renal mass biopsy based on 100% comparison of the preoperative samples with the surgical specimen is very low. For example, only 17 of the 57 studies included in the systematic review of Marconi et al. provided this 100% comparison [20] and only 56.4% and 16.9% of the malignant and benign histology BRTs, respectively, received surgery in the systematic review of Patel et al. [8].

Accuracy in the diagnosis of RCC varied from 40% to 94% in the three studies before 2001 included in the review of Lane et al. [70–72]. The rate of biopsy failures varied from 0% to 22% and the rate of indeterminate biopsies from 4.3% to 36%. False positives were almost nonexistent (0–2.2%), but false negatives accounted for 0–24%. These results were clearly insufficient to justify the systematic use of percutaneous biopsy in the diagnostic setting. However, comparison with modern data is precluded as different needles, mostly 21G and 22G, were used, and in two of those studies biopsy was guided by old ultrasound devices.

After 2001, three more reports in the review by Lane et al. compared the percutaneous renal mass biopsy in all cases with the surgical specimen [66, 73, 74] (Table 124.3). The sensitivity of percutaneous core biopsy to detect malignancy proven at surgical specimen varies from 91.4% to 93.5% and the NPV varies from 50% to 81.3%. The rate of nondiagnostic biopsies was very low in these three modern studies, in the range of 2.4–7.1%, although in some cases a repeat biopsy was necessary to reach a diagnosis. Correct RCC subtype determination varied from 77.5% to 91% and correct Fuhrman nuclear grade from 51.5% to 76%, with the grade mainly being underestimated on CB.

## Biopsy in small renal masses

Because of the increasing diagnostic incidence of SRMs (≤4 cm), the high percentage incidence of benign masses among these kidney tumors [23, 75], and the difficulty of radiological distinction between malignant and benign in this size range, biopsy of SRMs has gained interest in recent years. At present, biopsy of SRMs is advised in major guidelines with the possible exclusion of those patients in whom watchful waiting or nonsurgical management is chosen [1–3, 10, 24]. In spite of the low biologic potential of small RCC, some may still exhibit a high grade [25, 29]. The clinical scenario becomes more complicated when considering that a large number of these SRMs are accidentally found in the elderly with comorbidity. In SRMs, a preoperative histologic diagnosis may lead to a change in management.

In general, sensitivity of renal biopsy in SRMs has been reported to be lower than in series including all tumor sizes. The recent literature challenges this result and reports show very high sensitivity and specificity of biopsy of small renal tumors, both close to 100% [8, 20]. However, biopsy failure rate and nondiagnostic rates should be expected to be higher in SRMs than in series including all size tumors. A rate of biopsy failure as high as 37% has been reported in renal masses smaller than 3 cm versus 9% in tumors larger than 3 cm [65]. The likelihood of biopsy success increases with every centimeter increase in the size of the SRM [76].

Table 124.4 gives an overview of published studies on biopsies in SRMs. As expected, biopsy of SRMs is less accurate than that in larger masses, with histologic confirmation by means of surgical specimen in 30–78% of cases [22]. The rate of nondiagnostic biopsies is also higher in SRMs, either because of technical failure or because of indeterminate results [10].

## Accuracy for histology and grade

Kidney tumors show intratumoral heterogeneity and therefore subtype identification can be misleading when biopsies are assessed. An overall accuracy of 94% in identifying the correct histologic subtype has been

**Table 124.3** Modern series on percutaneous renal mass biopsy with pathological confirmation (surgical specimen) in all cases.

reported [34]. When the result of a biopsy is malignant, subtype determination is possible in 93% of the biopsies; however, IHC is necessary in a substantial number of cases. Concordance with the surgical specimen is high (91–100%) [77, 78].

In recent systematic reviews agreement of BRT with histologic subtype is good ($k = 0.683$) or substantial [8, 20].

Fuhrman nuclear grade is correctly assessed in biopsy in approximately 68% of cases, with a lower concordance than for subtype (60–100%) or otherwise fair agreement ($k = 0.34$) [8, 20, 77–79]. Fuhrman upgrade from low in BRT to high in the surgical specimen occurs in 16% [8]. Similar results for grade accuracy have been reported for SRMs, although IHC is necessary in a substantial number of cases [8, 20, 77–81].

One of the major problems in differentiating subtypes of RCC is the distinction between oncocytoma and chromophobe RCC, since hybrid tumors containing areas of benign oncocytoma and malignant chromophobe RCC exist [74]. This issue remains a challenge for the pathologist, especially when limited tissue is available, as is the case with biopsies. New auxiliary techniques, such as genetic profiling, polymerase chain reaction (PCR), and FISH are under development to distinguish chromophobe RCC, oncocytomas, and other subtypes of RCC with more accuracy [43, 44, 82, 83].

Heterogeneity of renal tumors also hinders correct determination of Fuhrman's nuclear grade by biopsy. In two large recent series, Fuhrman's nuclear grade was correctly determined in 70% [64] and 83% [55], respectively. In all the discordant cases, the actual grade found in postoperative pathology was within one grade of the grade found at biopsy. A higher accuracy (76–100%) is obtained when the nuclear grade of tumors is grouped into "low grade" (Fuhrman I–II) and "'high grade" (Fuhrman III–IV) [64, 65].

## Biopsy during thermal ablation

When performing thermal ablation of small renal tumors, such as cryoablation or radiofrequency ablation (RFA), information on the pathology of the ablated mass can only be gained through biopsy of the tumor, since the specimen is not extirpated. Because this information not only is useful diagnostically but also may impact follow-up policy, biopsy should be performed before or during ablation [2, 3, 10]. An additional use of biopsies in the frame of ablation therapy is in determining the presence of residual tumor.

Two recent meta-analysis have compared cryoablation with RFA [84] and percutaneous ablation with surgical ablation, including laparoscopy [85]. Biopsy of the mass was performed in 82.3% of the cryoablations, in 62.2% of the RFAs, in 84% of the percutaneous procedures, and in 88% of the surgically assisted ablations [84, 85]. Overall, between 54% and 64% of the biopsies confirmed RCC, 12.7% showed benign pathology, and 33.5% had unknown or undetermined pathology [84]. With the limitations derived from the lack of well-designed comparative studies, it becomes evident that biopsy of the tumors is widely adopted during ablation treatments, except in the case of RFA where 40% of the patients are still treated without information on tumor biology [10].

The rate of nondiagnostic biopsy varies from 0% to 23% in those series of percutaneous ablation [86–89] and from 0% to 30% when tumor biopsy is performed during laparoscopic ablation [90–95]. These figures are similar to the nondiagnostic rates described for SRMs (see Table 124.4) as the tumors treated by ablation are in this size range. At least during laparoscopy-assisted ablation, modification of the biopsy technique by activating the firing mechanism of the biopsy gun externally to the target tissue led to a higher diagnostic yield in a small clinical series [92]. The criteria classifying a biopsy as nondiagnostic or benign vary between groups, which may explain the broad range of nondiagnostic or benign results. For example, normal renal tissue, fibrotic tissue, or necrotic tissue are distinctly classed as benign by some and nondiagnostic by others [93, 95]. In fact, the stricter the nondiagnostic criteria are, the higher the nondiagnostic rate of the biopsy.

Tumor biopsies can also be taken immediately after ablation to minimize risk of bleeding or tract seeding. In this situation, the pathologist can identify RCC architecture both after RFA and cryoablation and the diagnostic yield of biopsies before and immediate after ablation is not statistically different [96–98].

Success after ablation therapy is mainly determined using cross-sectional imaging with contrast. Lack of contrast enhancement indicates absence of tumor recurrence [99]. However, the presence of viable tumors in the ablated area is not completely ruled out by the lack of enhancement on CT or MRI [100]. Therefore, some centers have performed an additional postablation biopsy to assess the success of the ablation. A study on the correlation of radiographic imaging and histopathology showed that in 24% of patients treated by RFA, the biopsy taken six months after ablation showed viable renal cancer cells even though there were no signs of radiologic enhancement at that time [101]. The biopsy taken six months after cryoablation was consistently negative in all nonenhancing masses. Therefore, the sensitivity of nodular enhancement at six months after RFA to detect a positive biopsy was only 38.4%, with a specificity of 91.3%. The results for cryoablation were superior, with a sensitivity and specificity of 77.8% and 95.1%, respectively. In contrast, a study on RFA lesion biopsy more than 1 year after ablation showed no vital lesion [102]. It is therefore advisable to use nicotinamide adenine dinucleotide (NADH) or other oxidative stress stains when assessing biopsy after ablation [103].

## Additional pathologic methods

RCC subtyping was originally performed using a light microscope and standard H&E staining. The diagnostic accuracy in differentiating benign from malignant renal mass is substantial, but for determining RCC subtypes the accuracy is lower, since complex and overlapping morphologic features exist. As described earlier, this results in interobserver and intraobserver variability of subtyping [31, 32].

For a long time research to improve subtyping of renal tumors had no priority because there were no clinical consequences. However, there has been interest in subtype determination of RCC following the incorporation in clinical practice of targeted therapies. Correct determination of RCC subtype can be of importance since paradigms for specific RCC subtypes may not apply to other subtypes. Therefore, a more accurate differentiation of RCC subtypes is desirable.

Differences among RCC subtypes at DNA, RNA, and protein level have been explored in order to improve the accuracy of subtype differentiation. Although different subtypes of RCC show overlapping histologic features they are biologically distinct. This is obvious when the cytogenetic abnormalities of different subtypes are observed: different subtypes have characteristic abnormalities, such as chromosome 3p aberrations in clear cell RCC and trisomy 17 in chromophobe RCC [104]. These characteristic differences imply that the different subtypes are distinguishable by mapping this genetic expression.

One method of performing molecular gene profiling analysis is DNA microarray. This has shown differences in gene expression profiles between subtypes of RCC and therefore differentiates between the histologic subtypes of RCC [105–107]. By analyzing the mRNA expression ratios of different genes in different subtypes of RCC, the individual subtypes can be differentiated. High *CA9* expression in clear cell RCC, *AMACR* in papillary RCC, and *CLCNKB* in chromophobe RCC and oncocytoma [108] facilitates a molecular diagnostic algorithm. It has been demonstrated that renal masses can be accurately classified on CBs using a combination of histopathology and molecular gene profiling analysis [17].

In order to obtain sufficient material for investigation, the genetic material harvested with percutaneous biopsy should be amplified by PCR [17, 35].

Another auxiliary technique for subtype differentiation is IHC, which localizes specific antigens or proteins in a tissue sample by binding the antigens with labeled antibodies. The formed antigen–antibody complex can be visualized by (fluorescent) staining and therefore the presence of the antigen can be demonstrated.

Several antigens have been found to be useful as a marker for subtype determination of RCC, and they are currently used in combination with histologic investigation to improve the diagnostic accuracy. It is likely that in the near future these techniques will contribute more to the diagnostic process [109–111].

## Conclusions and recommendations

At present, biopsy of SRMs is recommended in the major guidelines, particularly in case of SRMs, before or during ablative procedures, and when treatment depends on histologic subtype determination. CB is more commonly performed than FNA. Complications are rare and mostly of low grade.

Modern series on percutaneous biopsy of renal masses show a high accuracy and a lower rate of nondiagnostic biopsies than previous reports. Series with pathologic confirmation by means of surgical specimen support these results, although NPV remains low. The concordance between BRT and pathology subtype determination is good/substantial, while the concordance in terms of grade remains fair.

However, when considering a percutaneous biopsy in an SRM, there needs to be awareness that although accuracy may reproduce the figures reported for the general series on percutaneous biopsy, the overall rate of nondiagnostic biopsy – either failed or inconclusive – is still high in SRMs and size dependent.

Biopsies should be systematically performed during ablation therapy, although a similar rate of nondiagnostic biopsies is expected as for SRMs in general.

Current percutaneous renal biopsy is recommended when there is a suspicion of nonprimary RCC, when an infectious cause is suspected, during ablation therapy, to decide on treatment of SRMs, for therapeutic purposes in metastatic RCC, and for documentation and follow-up purposes when a RCC is submitted to active surveillance.

# Radiofrequency Ablation of Renal Tumors

*Ryan L. Steinberg & Chad R. Tracy*

*University of Iowa, Department of Urology, Iowa City, IA, USA*

## Introduction

With the increasing use of cross-sectional imaging, there has been a dramatic increase in the incidental identification of asymptomatic small renal masses (<4 cm in size) [1], the majority of which are renal cell carcinoma (65–80%) [2, 3]. The risk of metastases at the time of surgery for such masses is low [4], as is the development of *de novo* metastases [5]. Although active surveillance may be appropriate for many of these lesions, most tumors will grow with serial imaging [6], albeit slowly (mean 0.26 cm/year), and may require subsequent treatment.

Traditionally, renal masses have been managed by radical nephrectomy, but nephron-sparing surgery, namely partial nephrectomy, has been accepted more recently for most T1a (<4 cm) and in some cases T1b (4–7 cm) renal tumors with the recognition that chronic kidney disease after radical nephrectomy may lead to increased patient morbidity and mortality [7, 8]. Multiple studies have shown that partial nephrectomy has similar intermediate- and long-term cancer-specific survival [9, 10] with only mildly increased complication rates [11]. Although traditionally performed in an open fashion, other than at centers with an expertly trained laparoscopic surgeon, recent advancements in robotics and minimally invasive technologies have driven a shift towards increased utilization of laparoscopic nephron-sparing surgery. Technical considerations, including location, tumor depth/size, or proximity to the collecting system/renal hilum [12], may also impact the decision-making process as to the optimal treatment modality for each small renal mass.

Despite the advantages of partial nephrectomy, many patients will not be good candidates for extirpative surgery due to comorbidities, the need for ongoing anticoagulation, prior intra-abdominal or renal surgeries, or intolerance of positioning or procedure length. Others may simply prefer a “less invasive” alternative. For these patients, percutaneous ablation may be a suitable alternative. Radiofrequency ablation (RFA) of tumors was initially described in the treatment of hepatic malignancies in 1993 [13] and later in the treatment of a kidney tumor in 1997 [14]. Soon after, Walther et al. assessed the effectiveness of ablation by performing RFA followed by immediate tumor excision and noted effective cell death in 10 of 11 tumors [15]. Multiple cohort studies with increasing follow-up duration have since noted good oncologic outcomes, low complication rates, and short postprocedural recovery times with RFA.

Given the success and good procedural tolerance, RFA is now an accepted alternative treatment modality for small renal masses [16]. Although all of the above benefits make RFA an appealing option, it is important to continually evaluate long-term oncologic data and enhance technique to maximize surgical outcomes. In this chapter, we review the technical aspects of RFA, as well as its mechanisms of action, indications for the procedure, complications, and outcomes.

## Mechanism of action

RFA ablates tissue using a monopolar, alternating electric current into the target tissues, typically at a frequency of 450–1200 kHz. Application of a high-frequency alternating current causes ions, namely water, within the tissue to continually realign with the current polarity, leading to vibration and kinetic energy. This leads to molecular collisions, friction, and, invariably, heat production. Importantly, the heat is not directly supplied by the probe itself, as is the case with other ablative therapies (i.e. cryotherapy), and the probe is not heated by the current [17]. Once a critical temperature is surpassed,

Companion website: www.wiley.com/go/smith/textbookofendourology

cellular protein denaturation and cell membrane disintegration occur, resulting in cell death.

Early reports assessing the critical temperature and duration necessary to induce tissue destruction identified irreversible cellular injury with >99% cell death when the tissue was heated to 55 °C for 30 minutes, 60 °C for 10 minutes, and 65 °C for 8 minutes in an *in vitro* model of human renal cell carcinoma [18]. Histopathologic analysis of treated lesions demonstrates coagulative necrosis, membrane disruption, protein denaturation, and vascular thrombosis [19], as well extensive cellular edema, localized tissue inflammation [20, 21], loss of nuclear detail and nonvisualization of nucleoli [15] within hours of ablation. Further nuclear degeneration and chronic inflammation will occur by 3–7 days post ablation, total loss of renal architecture with complete loss of cytoplasmic borders by 30 days, and near total resorption of necrotic tissue by 90 days [20, 21].

## Indications

Clinical indications for RFA are based on both patient factors and tumor characteristics. Initial reports suggested that RFA be reserved for patients at high risk for surgery due to comorbidities, compromised baseline renal function, and/or multiple tumors. Currently, the European Association of Urology (EAU) makes “no recommendation” on the use of RFA for small renal masses “owing to the low quality of [the] available data” [22], while the American Urological Association (AUA) recommends that RFA be considered as a first-line therapy for patients with major comorbidities or at increased surgical risk and a clinical T1a renal mass [16]. The AUA guidelines also consider RFA an option for healthy patients with a clinical T1a renal mass or patients with major comorbidities or at increased surgical risk and a clinical T1b renal mass.

At our institution, patients are considered candidates for RFA if they have a solid small renal mass with contrast enhancement (≥15 Hounsfield units [HU]) on computed tomography (CT) or magnetic resonance imaging (MRI), which is located >1 cm from surrounding structures, including the ureteropelvic junction (UPJ). In patients who meet this criteria, a thorough discussion is had regarding both ablative and extirpative treatment options, including both open and minimally invasive surgeries. The risks and benefits of the procedure are reviewed, including the good long-term outcomes of RFA [23, 24]. The typical recovery after both ablative and extirpative surgeries is also reviewed. The ultimate decision to proceed with RFA stems from shared decision-making. For those planning to pursuing RFA, the need for a more rigorous radiographic surveillance protocol and the possible need for repeat procedure (repeat RFA vs. extirpative surgery) if local recurrence were to occur is also reviewed.

## Contraindications

There are no absolute contraindications to RFA other than uncontrolled coagulopathy. However, there are a few relative contraindications that should be considered prior to proceeding with RFA. Patients unable to tolerate anesthesia or sedation can undergo ablation under local anesthesia but this is not as optimal given the difficulty controlling for patient movement and standardization of respiratory depth. Patients requiring blood thinners or with other coagulopathies should have these corrected prior to treatment [25]. Although some consider all T1 lesions to be amenable to RFA, T1b tumors have shown increased rates of recurrence and require multiple probes to be placed, thereby increasing the risk of complication. Thus, many, including the authors, would not advocate for the routine use of RFA for T1b lesions. Finally, hilar or centrally located tumors are at higher risk of complication after ablation due to the proximity to the renal pelvis and vasculature, as well as reduced ablative efficacy due to the “heat sink” effect of surrounding vasculature.

## Technical considerations

A thorough understanding of RFA equipment is critical to performing a safe and effective procedure. There are two types of RFA systems currently available: temperature-based and impedance-based systems. Temperature-based systems work by achieving a specified temperature for a preset duration based upon measured tissue temperatures at the probe tip during heating. Conversely, impedance-based systems work by delivering energy until a predetermined impedance level, or measured resistance to energy transmission, is achieved through surrounding tissues, thereby indicating tissue ablation. Incomplete ablation of tumors due to skip lesions has been identified more often with impedance-based technology, likely due to the indirect measure of impedance versus temperature [26].

Another consideration when selecting RFA technology is whether to utilize a wet or dry probe. If energy application is too sudden when ablating tissue, a charring effect can occur near the probe tip, leading to increased tissue impedance and limiting the ablation zone. This primarily occurs with a dry probe. Wet RFA probes infuse a constant stream of saline into the probe to minimize the chance for charring adjacent to the probe tip, allowing for a larger zone of tissue desiccation. Although the treatment area can be larger with the wet probes, the wider zone may provide less control over the targeted area and increase the chance of damage to normal adjacent parenchyma.

Varying array diameters (2–5 cm) and probe lengths are also available with each system. Given the inverse relationship between the induced tissue temperature and distance from the RFA probe (temperature ≈ 1/radius) [27], careful probe size selection, particularly in large T1a lesions, is crucial. In the end, the type and size of probe utilized should be tailored to each individual tumor.

Several devices are currently approved for RFA. The RITA device (Angiodynamics, Albany, NY, USA) utilizes an umbrella-shaped, multi-tine, dry probe with a temperature-based system controlled by thermistors embedded in five of the nine electrodes. Each electrode modulates energy delivery based upon the measured temperature, as well as the mean electrode temperature. The LeVeen system (Boston Scientific, Natick, MA, USA) is an umbrella-shaped, multi-tine dry probe with impedance-based system. The Valleylab system (Mansfield, MA, USA) uses an impedance-based system composed of a single, 17G ("cool tip") wet probe electrode. Although randomized human trials between these systems do not exist, a direct comparison in a porcine liver model demonstrated larger zones of ablation with the wet RFA probe systems, more spherical ablation with the 12-tinned electrodes, and better reproducibility with nine-tine electrodes [28].

## Tumor considerations

Circulating blood near the ablative site can act as a "heat sink" and remove energy (heat) from the surrounding tissues, thereby reducing the efficacy of the ablation. This is an important factor to consider given that the kidneys receive 20% of the cardiac output. Prior studies have found that vessels greater than 3 mm in diameter can produce a heat sink effect [17]. Temporary clamping of the renal hilum during RFA negates this effect, leading to an increased size in the procedural ablation zone and reduced time to target temperature, but no difference in ablation zone size after four weeks [29]. Thus, hilar clamping is not currently recommended due to increased risk (arterial thrombosis, ischemia–reperfusion injury) without added benefit. Some have advocated selective arterial embolization with RFA to achieve the same effect [30]. This may provide added benefit, particularly when ablation is to be utilized for a centrally located or large (≥4 cm) tumor.

Tumor location is critical to consider given the risk of injury to surrounding organs, namely the liver, spleen, bowel, and collecting system. Thus, any tumors within 1 cm of these structures or on the anterior portion of the kidney should be approached laparoscopically for ablation or with extirpative therapy. Alternatively, hydrodissection [31] with saline injection can develop a space for ablation, but this depends on surgeon familiarity and comfort. Posterior and lateral tumors, which are often far removed from these structures, can be ablated percutaneously under image guidance [32], although proximity to the body wall may also lead to postoperative complications.

## Procedural details

### Percutaneous radiofrequency ablation

Percutaneous treatment can be performed with either conscious sedation or general anesthesia depending on patient and surgeon preference. The authors prefer general anesthesia as it is safe for the majority of patients, enables control of respirations during probe positioning, and generally does not preclude same-day patient discharge when desired. Intravenous prophylactic antibiotics are administered prior to the procedure, with culture-directed antibiotics for anyone with a history of urinary diversion or preoperative evidence of urinary tract infection. Following urethral catheter placement, the patient is positioned on the CT gantry, being sure to properly pad all pressure points. The choice of position is largely dictated by the tumor location and patients may be placed completely prone or in a modified flank position.

Identification and treatment of the tumor proceeds in a repetitive, step-wise process. Due to the cumulative risk of radiation in this population of patients, it is essential to be mindful of each step in the ablative procedure [33]. Tumor localization is performed using an initial helical scan incorporating the entire region of the kidney with settings of 100–150 mAs and 120 kV. Once identified, the tip of the probe is placed up to the edge of the tumor along the expected trajectory required for treatment. For more anteriorly located tumors, a 5% dextrose solution in water is infused into the perinephric space to increase the distance between the renal lesion and closely neighboring structures, such as bowel. Probe placement is then performed utilizing repetitive CT scans at lower settings of 70–100 mAs and 120 kV, limiting the number of images to 3–6 per scan. At the authors' institution, a 14G Starburst XL (Angiodynamics) probe is then deployed and its position is adjusted to ensure complete lesion coverage plus a peritumoral margin of at least 5 mm. A confirmatory helical scan is then performed in order to confirm adequate coverage for the targeted treatment area. Depending on renal function, intravenous contrast is administered in order to define the deep renal margin (50% total normal dose). If no preoperative biopsy is available, an 18G TruCut biopsy may be performed by inserting the biopsy needle parallel to the ablation probe, with confirmation based on repeat imaging. Although the vast majority of our patients undergo preoperative biopsy, for those requiring an intraoperative biopsy, it is our preference to perform the biopsy after probe placement so that any bleeding from the biopsy does not obscure probe positioning. If there is bleeding from the biopsy site, ablation can proceed as planned as bleeding will be rapidly mitigated by the subsequent treatment.

Ablation cycles of 5, 7, and 8 minutes at a target temperature of 105 °C are delivered for tine deployments of <2 cm, 2–4 cm, and ≥4 cm, respectively, with two cycles delivered per treatment. During the brief intervening period between treatment cycles, the passive tissue temperature in each quadrant should be at least 70 °C. Once the ablation is complete, a final helical scan at 100–150 mAs and 120 kV can be utilized to look for perinephric bleeding and procedural complications. Depending on renal function, contrast may be administered to define a lack of enhancement (50% total normal dose) and determine early procedural success. If inadequately treated areas are identified, the radiofrequency probe is repositioned and the treatment is repeated. The probe tract is then ablated during probe withdrawal, maintaining a temperature of 70 °C up to the level of the fascia.

See accompanying Video 125.1 .

### Laparoscopic radiofrequency ablation

Laparoscopic RFA may be used for ablation of anterior or centrally located tumors. A transperitoneal approach is generally used. The kidney is mobilized, Gerota's fascia is entered and the lesion is exposed. The radiofrequency probe is inserted percutaneously through a separate stab incision and is deployed under laparoscopic ultrasound guidance, ensuring that the treatment tines extend beyond the tumor edge and the deep margin. At conclusion of the treatment cycles, a 5 mm toothed forceps may be used to obtain a biopsy of the mass, followed by reapproximation of Gerota's fascia prior to port removal and closure.

## Postoperative surveillance

The National Cancer Center Network (NCCN) recommends surveillance with a history, physical exam, and comprehensive metabolic panel every six months for 2 years, then yearly until 5 years post ablation. Surveillance imaging should include yearly chest X-rays for 5 years, initial abdominal imaging 3–6 months post ablation, and yearly abdominal imaging for 5 years [34]. At our institution, we follow the above NCCN protocol with the exception that a contrast-enhanced CT or MRI is performed at six weeks post ablation to look for early success and in order to define recurrence versus incomplete ablation. All images are reviewed by both a radiologist and urologist to evaluate for any remaining tumor or recurrence.

It is important to note that during ablation, along with coagulative necrosis and tissue desiccation, significant localized inflammation will occur around the ablation bed. Thus, immediate post-RFA imaging will show circumferential high attenuation around the ablation zone, which is a normal finding that can be mistaken for persistently viable tumor [14, 35]. In actuality, this area corresponds to a hyperemic inflammatory response of surrounding normal parenchyma, as shown on histologic inspection. True ablative effects cannot be fully appreciated until completion of coagulative necrosis at seven days after the procedure [15]. As mentioned above, complete destruction of renal architecture and cytoplasmic border loss may take weeks to occur; thus, waiting for six weeks to perform initial imaging allows sufficient time to accurately assess for incomplete versus successful ablation.

## Defining treatment failure

Any enhancement within the ablated zone on the initial imaging or enlargement of the lesion regardless of enhancement is considered an incomplete ablation. The most common finding when incomplete ablation is identified is a crescent-shaped area of enhancement on the medial margin of the ablated zone (Figure 125.1). This should be differentiated from recurrence, which is defined as enhancement within the ablated zone after a normal initial CT or MRI. Although incomplete ablation is typically found on the periphery, recurrence can occur at any location within the ablation zone. Importantly, lesions treated with RFA will demonstrate a characteristic fibrotic halo or circular demarcation around the treatment zone representing a foreign body giant cell fibrotic response [36]. This should not be misinterpreted as persistent or recurrent disease (Figure 125.2). Unlike cryoablation, involution of ablated lesions may not routinely occur, and thus should not be used as a marker for success. The two most important requirements for determining radiographic success of RFA are a lack of growth within the ablated lesion and lack of contrast enhancement [37].

Although an imaging-based definition for success has been most utilized, some question its validity [38] given that post-ablation biopsies may show intact tumor cells on

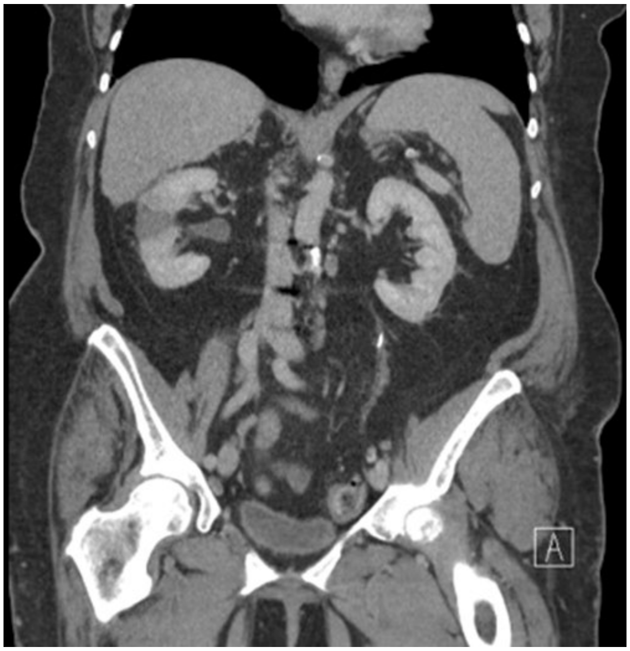

**Figure 125.1** A 75-year-old female 6 weeks after right percutaneous radiofrequency ablation showing incomplete ablation with nodular enhancement at the superior aspect of the ablation zone. The patient underwent a secondary ablation with no evidence of enhancement at subsequent six-week follow-up.

hematoxylin and eosin (H&E) staining. However, cellular viability as determined by nicotinamide adenine dinucleotide (NADH) diaphorase staining routinely demonstrates a lack of cellular viability [39, 40] in light of maintained architecture. In addition, Anderson et al. found that 14% of biopsies done within 150 minutes of ablation showed viable tissue in a porcine model, while no lesion biopsies after 3 hours showed viability, suggesting that biopsies performed too close to the time of ablation do not accurately characterize the full RFA ablative effect. Therefore, the timing of biopsies and method of staining after RFA are essential when evaluating for cellular viability and should be interpreted carefully. Given the difficulty in interpreting immediate post-RFA biopsies, we do not currently recommend postoperative biopsy in patients with good radiographic response to RFA.

## Complications

The overall complication rate following RFA is 8–11% [41–43], with a 4–6% rate of major complications [16, 43–46]. Multiple studies have also suggested a higher rate of complications with laparoscopic ablation [46, 47], as compared to percutaneous, due to laparoscopic technique [41], but rates remained lower than those for extirpative procedures [16]. Importantly, with increasing experience complication rates, regardless of surgical approach, decrease [41, 46].

The two most common complications of percutaneous RFA are bleeding and postoperative pain. Perinephric, subcapsular, or retroperitoneal hematomas can be seen in 3–6% of all patients and are typically managed conservatively. Tumors >3 cm in size are noted to have higher complication rates, primarily due to hemorrhage [48]. Pain and/or parasthesias at the probe site occur in up to 8% of RFA patients [42, 49], although the incidence has decreased over time. Evolution of ablation probe design with an insulation sheath, careful grounding pad placement, and maximizing the renal-body wall distance with positioning or hydrodissection [50] can help avoid damage to posterior abdominal wall cutaneous nerves [50, 51]. Transient hematuria and increased serum creatinine are also commonly reported and can typically be managed conservatively with spontaneous resolution.

With respect to major complications, significant blood loss [46] and urothelial injury are the most common [43, 45] but constitute less than 3% of all complications. Hemorrhage requiring transfusion may occur in 1.4–4% of patients treated with RFA [16], but the need for selective angioembolization is quite rare. The main risk factor associated with significant hemorrhage is the placement of multiple probes for larger renal masses. Bleeding during percutaneous needle placement can be controlled by proceeding with the ablation given the coagulative nature of RFA, while bleeding during laparoscopic ablation can be managed with hemostatic agents and/or direct pressure. Abdominal wall bleeding, namely from the intercostal arteries, can also occur and is typically identified as an expanding hematoma during routine imaging at the conclusion of the procedure. Bleeding at this point in the procedure should be evaluated for severity by performing serial scanning at 10 minutes after the ablation and prior to awakening the patient from anesthesia. If the hematoma is rapidly expanding or the patient becomes unstable, angiographic embolization may be required. Urothelial injury most commonly presents as a urine leak and may require ureteral stent placement with or without percutaneous drain placement depending on the severity of the urinoma. Other urothelial-related injuries, including ureterocutaneous fistula [52] and ureteral/UPJ stricture formation [43, 45], understate the need for careful tumor selection when in juxtaposition to the UPJ or upper ureter.

Damage to surrounding organs, including liver, pancreas, spleen, colon, and pleural cavity are exceedingly rare and can be minimized through appropriate patient selection, preoperative planning, and good surgical technique. Often these injuries occur in patients with anteriorly located tumors, tumors in close proximity to the collecting system, or tumors without a suitable access

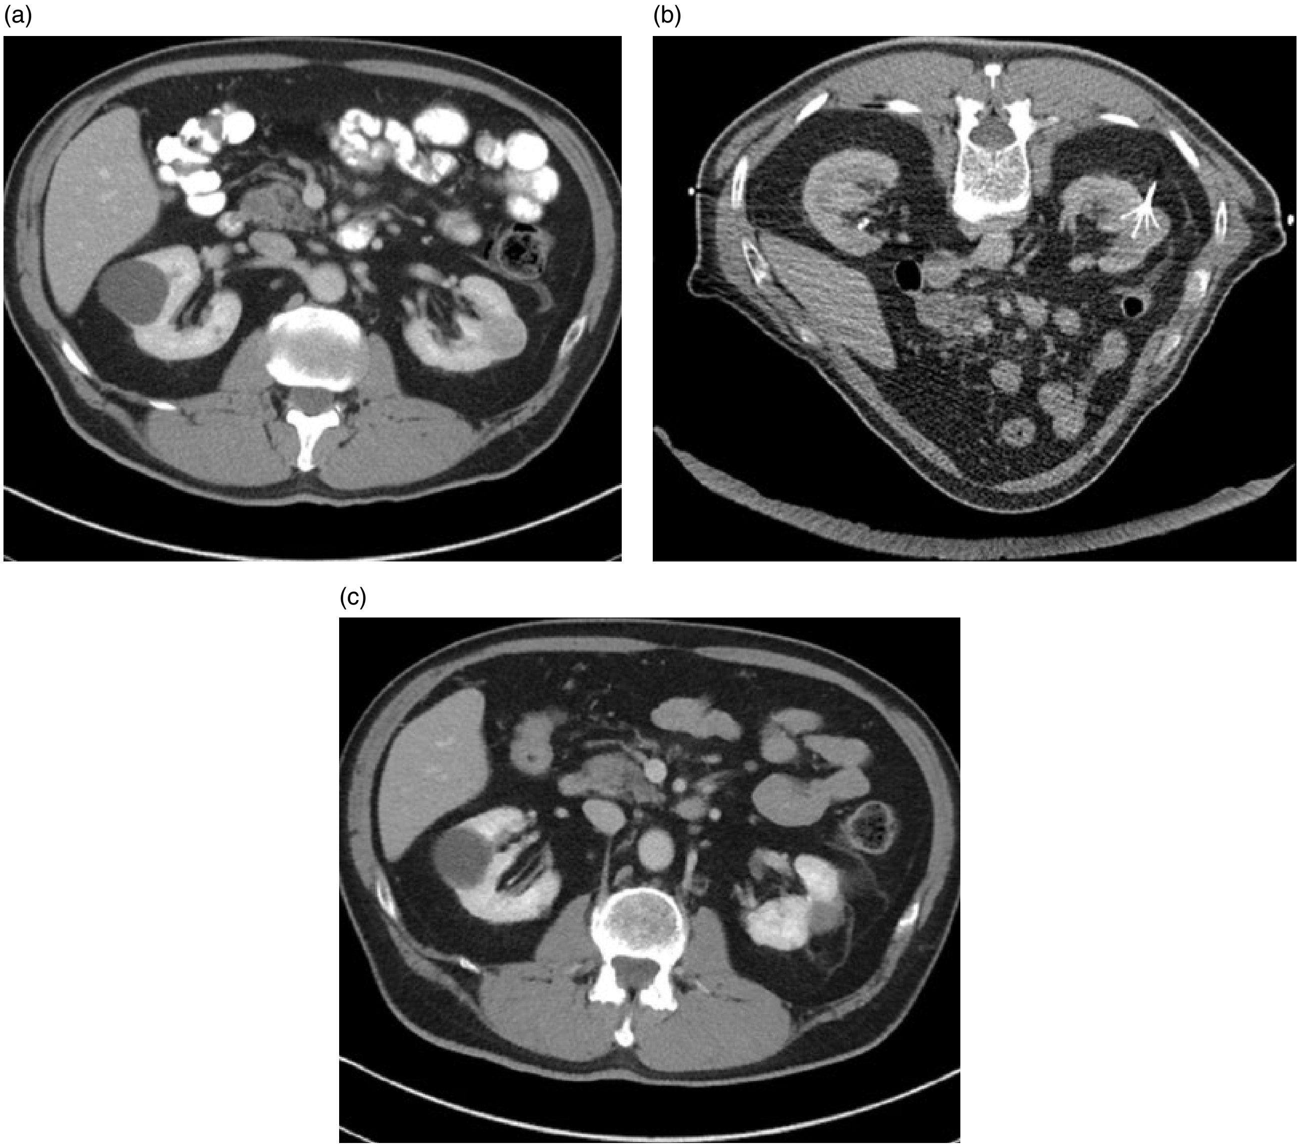

**Figure 125.2** A 63-year-old male with biopsy-proven 2.5 cm left renal cell carcinoma (R.E.N.A.L. nephrometry score = 8). (a) Preoperative axial CT. (b) Intraoperative tine deployment. (c) Postoperative CT at six months showing hyperdense area with lack of contrast enhancement and characteristic peritumor "halo."

tract for needle placement on preoperative imaging. Recognition that such injuries can occur and early identification of these injuries is paramount.

Injury to the pleural cavity, most often a pneumothorax or hemothorax, can occur with probe placement above the 12th rib. These complications are typically recognized during the procedure as either ventilation difficulties or, with percutaneous access, on routine imaging (Figure 125.3). If a simple pneumothorax is identified, it can be treated by aspiration using a small needle inserted into the pleural space at the conclusion of the case. If a large or persistent pneumothorax or large hemothorax is noted, placement of a chest tube should be performed. Postoperative chest pain or dyspnea should trigger suspicion of such an injury and prompt an upright chest radiograph.

Colonic injury should be managed in conjunction with a general surgeon given the spectrum of injury that can occur. In the setting of a frank colon perforation with signs of peritonitis, prompt surgical exploration should be undertaken. Colonephric fistulas can form and can be managed initially with placement of a ureteral stent. Patients with a persistent fistula or colocutaneous fistula may require surgical diversion or a trial of total peripheral nutrition. In tumors with close proximity to bowel, hydrodissection by injection of saline into the plane

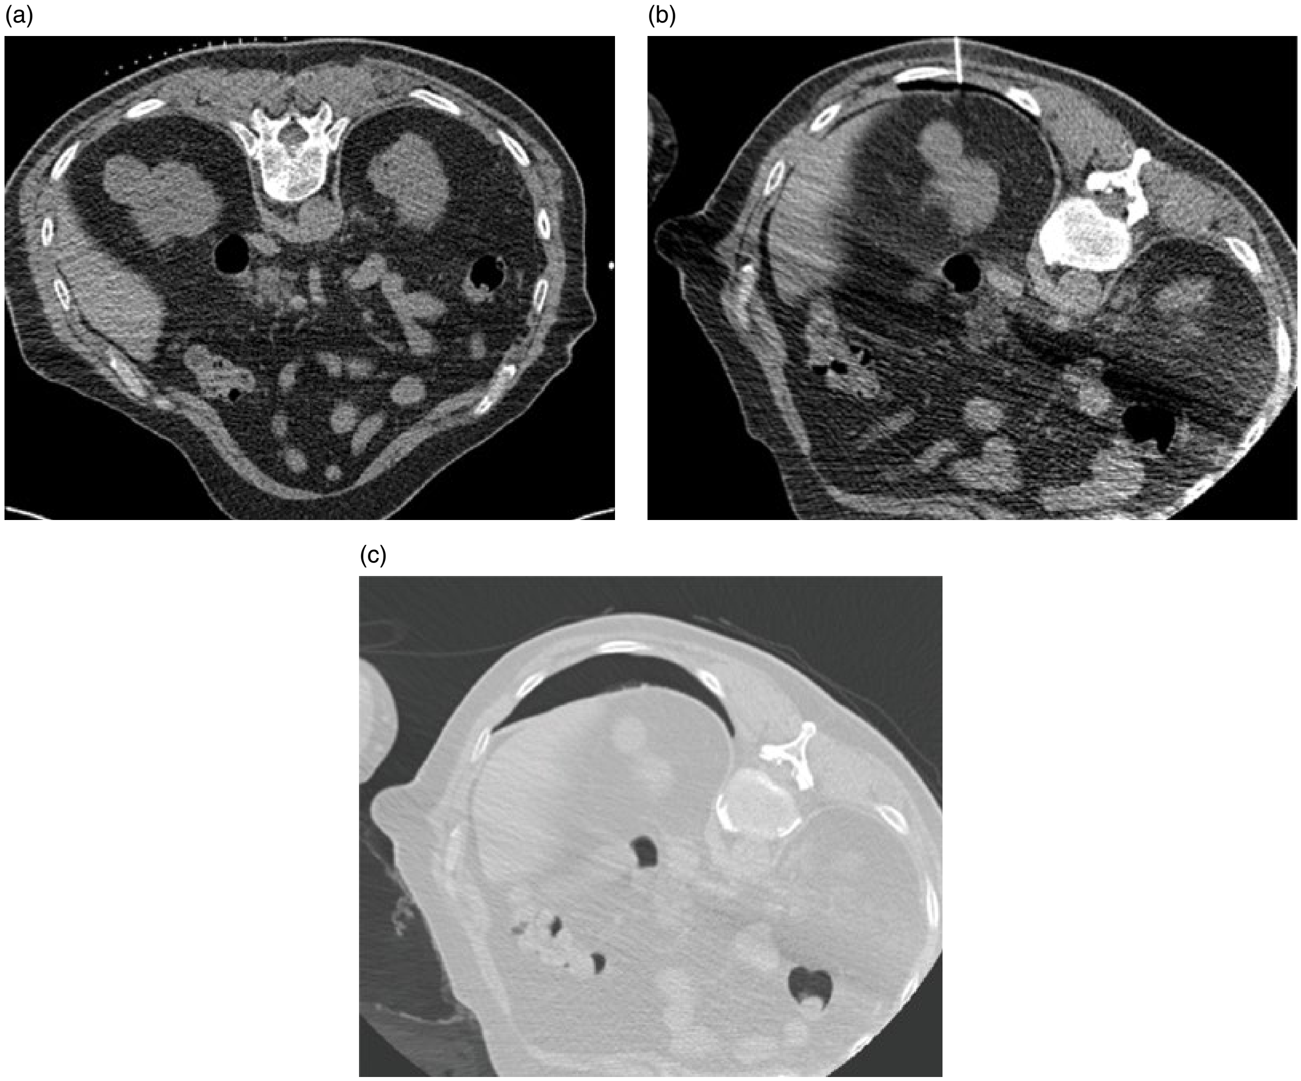

**Figure 125.3** A 71-year-old with 3 cm right renal cell carcinoma. (a) Initial imaging does not indicate the presence of the pleural space. (b) During placement of the probe intraoperatively, the needle is seen to be traversing the pleura. (c) Lung windows demonstrate expansion of the pneumothorax, which prevented percutaneous ablation at this setting. The pneumothorax resolved spontaneously and the patient subsequently underwent percutaneous ablation with a more inferior needle placement three months later.

between the tumor and colon can develop a safe working space around the tumor [31, 50] but ultimately depend on surgeon comfort and familiarity with anatomic landmarks.

Postoperative infection following ablation, in the absence of a large hematoma or urinoma, is exceedingly rare but may be lethal [53]. Patients most at risk for infection are those with chronic colonization of the urinary tract (e.g. ileal conduit) or active infection at the time of the procedure [52]. When infectious complications do occur, they typically present in a delayed fashion (1–6 months post procedure) as chronic drainage or a retroperitoneal abscess. Patients at risk for urinary tract infection should be screened by urine culture and treated appropriately prior to their ablation procedure. We routinely administer perioperative prophylactic antibiotics at the time of the surgery at our institution.

In an effort to objectively determine the risk of complications, several authors have attempted to utilize the R.E.N.A.L. nephrometry score [54], as has been done with extirpative therapy [12], to predict the risk and severity of RFA complications. Many conflicting studies have been reported and the debate is ongoing [53, 55].

## Overall outcomes

In considering the existing literature, there are multiple confounding factors that make interstudy comparisons difficult, including ablative technique (laparoscopic vs.

percutaneous), small cohort sizes, lack of uniform preablation biopsy, short-to-moderate follow-up, inclusion of patients with hereditary cancer syndromes, and variable definitions of recurrence. However, taken together, over intermediate-to-long follow-up, local recurrence-free survival can be expected in up to 88–95% of patients at 3–5 years [23, 24, 44, 47, 56–59].Both metastasis-free survival (87–100%) and cancer-specific survival (97–100%) [23, 45, 56, 57, 60] are excellent and similar to that reported for partial nephrectomy. Table 125.1 summarizes the most recent long-term series of RFA outcomes.

Although overall survival is an important metric in any study, its significance in the study of RFA tends to represent the patient population being treated rather than the oncologic nature of the cancer. Patients undergoing RFA tend to be older and have higher comorbidities than those undergoing extirpative surgery [16, 62]. Multiple large series have reported an overall survival of only 75–85% at 5 years [24, 60, 62], but with the recent shift to offer RFA to a less morbid population, along with refinement of the technique, excellent overall survival rates with medium-length follow-up have been reported (98–100%) [23, 56, 57]. Further assessment of these patients for long-term durability (10 years) will help to better shape the role of RFA in younger and healthy patients.

Comparison among ablative therapies is challenging for the aforementioned reasons, but, in experienced centers, there does not appear to be a difference in oncologic outcomes between RFA and cryoablation [16, 59, 63]. Furthermore, experience to date suggests that progression-free survival and disease-specific survival are similar for RFA and extirpative therapy (both exceed 90%). Two single institution comparisons have shown similar rates of local recurrence between RFA and PN [56, 62], but reached opposite conclusions regarding metastasis-free survival likely due to patient selection bias.

One other major advantage to ablative therapy when compared to extirpative surgery is the minimal impact on overall renal function after intervention. Most reports suggest a modest 2–10 $\text{ml/min/m}^2$ reduction in glomerular filtration rate (GFR) following RFA [57, 64] and a significantly lower number of patients with new-onset stage 3 CKD [65]. Improved renal function preservation has also been shown when treating tumors on solitary kidneys [66], likely due to not clamping the renal hilum and the precision of imaging guidance limiting the damage to adjacent normal parenchyma.

## Subgroup outcomes

As emphasized above, patient selection is very important when considering treatment options. The first parameter which should be considered is tumor size. While no specific cutoff has been established, RFA outcomes appear to be optimal in patients with tumors up to 3 cm. Best et al. noted a significantly higher 5-year disease-free survival for tumors <3 cm compared to those >3 cm (91% vs. 79%, $P = 0.001$) [67], while Psutka et al. identified a significant 5-year disease-free survival difference between T1a (91.5%) and T1b tumors (74.5%, $P = 0.003$) [60]. Although the AUA guidelines suggest that tumors greater than 4 cm may be treated by RFA [16], many centers avoid ablation of T1b tumors, regardless of comorbidity status, for these reasons. When RFA is reserved for smaller tumors, several studies report oncologic efficacy similar to that for partial nephrectomy [68, 69].

Other tumor characteristics beyond size are important in assessing RFA efficacy. Schmit et al. demonstrated that increasing tumor complexity, as measured by R.E.N.A.L. nephrometry score [54], is correlated with increasing treatment failure [53]. However, many patients undergoing RFA fall into the lowest or intermediate-risk groups based on tumor size cutoffs, making it difficult to discern risk between low nephrometry tumors in predicting procedural risk. Gahan et al. used a modified nephrometry score (adjusting the size scoring to be 1 point for <3 cm, 2 points for 3–4 cm, and 3 points for >4 cm) in 192 patients with moderate follow-up (32 months) [70]. No difference in initial ablative success or 3-year recurrence-free survival was noted with standard nephrometry scoring, but the modified score ("R-score") was significantly associated with both initial ablative success and 3-year recurrence-free survival. In addition to size and location, which are the primary measurements for the R.E.N.A.L. nephrometry score, preoperative tumor enhancement of >60 HUs has also been shown to be independently predictive of an incomplete initial ablation [71], potentially due to heat sink from highly vascular tumors.

Some authors have reported inferior initial treatment outcomes with the percutaneous approach compared to the laparoscopic approach but with similar effective treatment rates after a secondary procedure [46]. This is likely due to less aggressive initial treatments with RFA compared to those undergoing extirpative treatment, given the perception that percutaneous treatments are easily repeatable. Surgeons performing percutaneous ablation, therefore, may be more accepting of persistent disease on short-term follow-up, presuming that the tumor may be completely ablated with a second, minimally invasive procedure.

Other considerations include advanced age (>80 years old), which showed good efficacy and no major complications in a small series [72], as well as improved outcomes in patients with papillary disease (vs. clear cell) [73]. The latter has been postulated to be due to the less vascular nature of papillary tumors leading to less heat

**Table 125.1** Intermediate and long-term outcomes after radiofrequency ablation for renal tumors.

loss during ablation. Further evaluation is warranted to better highlight those patients who would optimally benefit from ablation.

## Conclusions

Given the currently available data, RFA is an acceptable alternative treatment modality to extirpative therapy for small renal masses (<4 cm). RFA has similar oncologic outcomes to extirpative therapies as well as low rates of morbidity and good preservation of renal function. With appropriate patient selection, oncologic outcomes with RFA appear similar to other ablative therapies, as well as partial nephrectomy. RFA is technically less challenging than partial nephrectomy, though learning curves exist for patient selection, tumor targeting, probe deployment, and generator use. Characteristics that have been shown to make a tumor particularly amenable to RFA include posterior location, <3 cm, enhancement less than 60 HUs, >0.5 cm from the ureteropelvic junction or renal pelvis, and >1 cm from surrounding bowel. Ultimately, the decision to treat a small renal mass with RFA should be decided on an individual basis taking into consideration tumor-related characteristics, patient demographics, patient comorbidities, and patient preference.

## Introduction

Renal cell cancer (RCC) represents 2% of adult cancers and is the third most common urinary tract malignancy [1–3]. Disease epidemiology is poorly understood, although smoking, obesity, and acquired cystic renal disease have been identified as risk factors [1]. The natural history of renal cancer is typically one of a long period of indolent growth in asymptomatic patients. Clinical presentation on the basis of symptomatology usually indicates advanced disease, with metastasis likely, portending a poor prognosis. The advent of modern imaging, combined with changing diagnostic algorithms and practices, has led to a serendipitous increase in diagnosis of small renal tumors. It is estimated that as many as 70% of diagnosed renal tumors are stage T1a. Small renal masses within this size range have been shown to grow at an average rate of 0.3–0.4 cm/year and exhibit a very low rate of progression to metastatic disease [1–4]. Of small renal masses, 80% represent RCC, but approximately 20% are benign [1]. This raises the management dilemma of active surveillance or extirpative therapy; the more aggressive approach, while definitively treating the tumor, would lead to the treatment of many indolent tumors of uncertain malignant potential [5]. An important concept in the management of renal tumors is cytoreductive therapy. No matter how large or the extent of metastatic disease, there still appears to be benefit to treatment in most situations. The Southwest Oncology Group 8948 and European Organization for Research and Treatment of Cancer (EORTC) 30947 trials demonstrated superiority of nephrectomy + interferon-α over interferon-α alone with 3- and 10-month survival benefit [6]. Patient selection is important for optimization of therapeutic benefit and efficacy. Currently, in most settings, ablation patients are typically poor surgical candidates, or those require nephron sparing, usually on the basis of prior resections and/or renal insufficiency. Typical patients have tumors of TNM staging T1a (limited to the kidney and less than 4 cm) [1]. In addition, it is the opinion of the authors that based on the current data, even good surgical candidates with lesions less than 2.5–3 cm in ideal anatomical locations, are also appropriate candidates for cryoablation. Finally, efficacy has also been demonstrated in treating T1b tumors (limited to the kidney and between 4 and 7 cm) but there is no question that based on oncological outcomes, patients in this category, who are likely to tolerate surgery with general anesthesia, should undergo nephrectomy [5].

## Historical perspectives

The first account of the use of cryotherapy to ablate tumors was by James Arnott in the 1800s using combination of ice and salt applied topically to palliate breast and cervical cancer [7, 8]. Topical techniques were further refined in the early 1900s with the use of compressed air, and eventually compressed liquified $CO_2$ to treat dermatologic conditions [9]. By 1967 Ortved et al. published a report of 100 cases using intense cold from liquid nitrogen to ablate tissue from the obstructed prostate gland [10]. Renal cryosurgery followed in 1968 by Lymberopoulos [11]. A shift from liquid nitrogen-based systems to argon gas-based ones occurred in the 1970s and entered mainstream use by the 1990s. This enabled a substantial reduction in probe size, allowing for percutaneous applications [7]. While gaining traction in the treatment of liver tumors in the early 1990s, popularity declined soon after, which some have attributed to

complications such as cryoshock or tissue “craking.” Cryoshock is believed to be a cytokine-mediated systemic response to cryoablation that results in hypotension, decreased renal function, coagulopathy, respiratory dysfunction, and multiorgan failure. Although this phenomenon was believed to be relegated to hepatic tumor ablations, usually during open procedures, it was not until the late 1990s that tumor cryoablation, in all organs, saw the resurgence in interest that has resulted in its routine use today.

## Physical principles of cryoablation

Cryoablation utilizes the Joule–Thomson effect, by which a high-pressure gas cools as it expands [7]. A closed circuit of high-pressure argon or nitrogen is passed through a metallic probe, resulting in formation of an iceball around the probe. In contrast, helium warms during expansion, enabling its use in some of the available systems for thawing and to facilitate probe removal [7].

The destruction of tissue is achieved via a number of mechanisms, both direct and indirect, which occur at various phases in the freeze–thaw cycle.

### Direct cellular injury

During the freeze phase, temperatures rapidly reach −165 °C to −190 °C in the region immediately surrounding the probe. Ice crystals form predominantly in the extracellular space. The resultant osmotic gradient draws water out of the cell, leading to cellular dehydration. The osmotic pressure that develops during freezing due to water flux is sufficient to cause rupture of cellular plasma membrane. As intracellular ice crystals form, protein denaturation damages organelles, leading to cellular death.

During the warming phase, ice crystals coalesce into larger crystals, which disrupt the cellular membrane. In addition, laboratory biochemical analyses suggest that decoupling of oxidative phosphorylation during this phase effectively halts the cellular machinery.

Warming initially affects extracellular ice, causing a reversal of the osmotic gradient, which causes an influx of water, increasing cellular volume and leading to membrane rupture and cellular necrosis. Histopathologic analysis suggests that lethal intracellular ice crystal formation predominates in the region closest to the probe, while osmotic effects predominate at the periphery of the freezing zone [12].

### Indirect effects

Indirect effects occur via microvascular occlusion during freezing, with subsequent glomerular congestion and tubular necrosis [12]. During freezing, vasoconstriction and eventual cessation of blood flow to the ablation zone damages the vascular endothelium. During warming, vasodilatation occurs, increasing vascular permeability. Platelet aggregation occurs due to activation by the damaged endothelial lining, triggering microvascular thrombosis, acute ischemia, and hypoxia [12].

These mechanisms result in local ischemia and necrosis of the tumor and surrounding margin. In the long term, scarring and fibrosis have been demonstrated in the ablation zone.

Successful tissue ablation requires close monitoring of many factors, including the number of freeze–thaw cycles, rapid cooling, lowest temperature achieved, duration of ablation, and slow thawing. The lethal temperature of normal tissue is −19.4 °C, whereas the fibrous nature of tumor enables it to tolerate lower temperatures. Studies of different tissue and tumor types have shown a range of −20 °C to −40 °C to be ideal for tumor lethality when used with multiple freeze–thaw cycles. The additional benefit of multiple freeze–thaw cycles is attributed to more rapid cooling during successive cycles and increase of the frozen tissue volume.

## Treatment and techniques

### Extirpative therapy

For over 50 years, radical nephrectomy had been the standard treatment for RCCs. As high-resolution cross-sectional imaging has gained widespread use, renal tumors are diagnosed at an earlier stage, which some have referred to as a staging migration. This staging migration of renal cancer diagnoses has been accompanied by a shift in the treatment algorithms to include minimally invasive and nephron-sparing techniques [13]. Guidelines from the American Urological Association (AUA) published in 2009 reflect this shift and recommend partial nephrectomy for solitary renal masses if technically feasible. Radical nephrectomy, ablation, or active surveillance are recommended as alternatives based on tumor characteristics or patient-specific factors or preference [14]. Huang et al. wrote in 2015 that the number of partial nephrectomies eclipsed radical nephrectomies by 2009 [15].

Although partial nephrectomy currently remains the treatment of choice, ablation has become an attractive alternative in patients with comorbidities. Cryoablation, when compared to robot-assisted partial nephrectomy, demonstrated somewhat lower 5-year disease-free, cancer-specific, and overall survival rates of 83.1%, 96.4%, and 77.1%, respectively, in the cryoablation cohort versus 100%, 100%, and 91.7% in robot-assisted partial nephrectomy [16]. Cryoablation offers practical advantages over more invasive treatments. One such advantage over surgery is reduced intraoperative blood loss and postoperative hematoma. This has been attributed to absence of a need for renorrhapy or dissection of the hilum with vascular clamping. Ablation probes can be placed under image guidance in a peripheral manner, thereby avoiding larger vessels. Other complications are also fewer, namely urinary leaks and requirement for ureteral stenting. Adverse effects on renal function following either partial nephrectomy or cryoablation appear to be equally rare [17]. Short hospital stays have also been reported of 72 hours on average for partial nephrectomy compared to the usual practice of cryoablation being performed on an outpatient basis [17]. Finally, cryoablation offers easier localization and access to endophytic and posterior lesions [1].

## Other ablative technologies

The most studied minimally invasive ablation technologies are radiofrequency and cryoablation, although newer technologies are gaining traction, such as microwave ablation and irreversible electroporation. Cryoablation differs from these less in its clinical efficacy, and more in practical matters, which affect the overall precision and risk profile of the procedure.

One such distinction between cryoablation and other ablative techniques is the relative imaging conspicuity of the iceball; and laboratory studies have confirmed that cryoablation provides superior imaging of the forming iceball with both CT and grayscale ultrasound [12]. Although we understand that the very peripheral aspect of the visualized iceball is nonlethal, the ability to see the applied energy as opposed to just predicting this from the probe geometry, as in other thermal ablation techniques, allows for better confirmation of accurate probe placement and therefore lesion coverage during the freezing process.

Another advantage of cryoablation is the reduced anesthesia requirements when compared to heat technologies. A retrospective clinical trial performed by Allaf et al., comparing anesthesia data for both radiofrequency ablation (RFA) and cryoablation in populations with similar demographic and tumor characteristics, showed an overall decreased need for nacrotics in the patients undergoing cryoablation [18]. A much larger retrospective study by Truesdale et al. also noted overall less sedation (midazolam) and narcotic (fentanyl) medications required for cryoablation compared to RFA [19]. This is thought to reflect partial anesthetic effects of cold. Some theorize that the microvascular occlusive effects of ice formation may also mitigate the heat sink effects of ablation of tumors near vessels. Both studies anecdotally mention the requirement for sedation reversal in the RFA groups, which may support a higher level of patient safety and comfort with cryoablation.

Ablation procedures are often performed with CT guidance. As mentioned in the Procedure description section, with each pass, the patient is moved in and out of the CT gantry. Vigilance is thus required to ensure that the cables connecting the needles, as well as the gantry itself, do not dislodge or deflect the probes from their intended trajectory. Cryoablation probes are equipped with a stick mode, which lowers the temperature around the probe just enough to provide traction, further securing it within the patient [20].

There is always concern for collateral injury during percutaneous ablation procedures. Cryoablation is advantageous over the heat-based ablative technologies, as even when included in the cryoablation zone, damage to or rupture of the collecting system is still unlikely [7, 21]. Studies have shown that indirect injuries to the collecting system were less common than when using heat-based systems [22]. There is no urothelial injury in cryoablation, which enables the cryodamaged collecting system to heal in a watertight fashion, virtually eliminating leak or urinoma formation as a complication [7, 21]. In a retrospective review of 67 cases, where imaging demonstrated overlap of the iceball with collecting system, no cases resulted in urinoma [23].

## Radiofrequency ablation

If any clinical difference in outcome exists between RFA and cryoablation, it would require a large, high-powered study to elicit such differences as studies have shown virtually no difference in progression to metastatic disease [2, 3, 24]. A laboratory comparison of needle-based ablation techniques in animal models demonstrated skip areas in impedance-based RFA, whereas heat-based RFA and cryoablation resulted in complete necrosis of treated lesions [12, 14, 25].

Although studies have demonstrated a reduced risk of tumor seeding of the needle tract in either modality, RFA allows cauterization of the puncture tract to minimize seeding as well providing as potential hemostatic effect [7]. Newer cryoablation systems, however, also allow this function, enabling more rapid thawing as well as tract ablation.

Differences in technical success also favor cryoablation over RFA. Studies that include long-term follow-up have suggested fewer retreatments required in cryoablation compared to RFA [2, 3]. Finally, cryoablation results in significantly lower rates of local tumor progression compared to RFA [2, 3]. Nevertheless, complication rates between cryoablation and RFA are less clear and some studies have shown slightly higher bleeding complications in cryoablation compared to RFA [21].

Overall, the role of cryoablation may edge out RFA on the basis of economics and cost-effectiveness. In an economic analysis, patients undergoing RFA had a lower quality-adjusted life expectancy [13]. The cost of cryoablation is approximately US$3010, whereas RFA had costs of US$3231–6398 [13]. It is interesting to note that US-based cost-efficacy analysis showed active surveillance with later cryoablation to be the most effective approach [13, 26].

### Microwave ablation

Microwave ablation is a technology which has gained recent enthusiasm due to its success with liver masses. A form of heat-based thermal ablation, it utilizes electromagnetic waves, which are oscillated to cause polar water to vibrate, producing friction and heat. Cell death occurs from coagulative necrosis [27]. It is currently under investigation for RCC [13].

### Irreversible electroporation

Irreversible electroporation employs the use of electric probes to employ rapid alternating electric pulses to induce microscopic pores in the cell membrane, leading to tissue necrosis. Irreversible electroporation may allow for ablations closer to critical structures. This nonthermal technique requires close cardiac monitoring, general anesthesia, and neuromuscular blockade [7]. It is currently still under investigation [28, 29].

## Procedure description

Planning cryoablation of a renal mass depends on a multitude of anatomic and physical factors. At our institution, prone or slight lateral supine oblique positioning is preferred [30]. Moderate or deep sedation and a local anesthetic are administered prior to the procedure [29]. In prone patients in whom adequate ventilation and monitoring might be an issue, the authors have a low threshold for endotracheal intubation with general anesthesia, compared with the option of light or no sedation.

The lesion is localized with CT, and then a needle biopsy is usually performed with specimen provided to the pathologist or cytopathology technologist, who examines the specimen with touch prep within the procedure suite [29]. The lesion is localized with an initial unenhanced scan and intravenous contrast only used when it is unclear if the ablation zone is adequate to cover the tumor.

In planning a safe kill zone, attention to patient position and the consequent varying spatial relationships with adjacent visceral structures is required. Traditionally, a transperitoneal approach is utilized for anterior or anteromedial tumors and a retroperitoneal one for posterior and posterolateral tumors [1]. The ideal distance of the kill zone from the renal hilum is at least 5 mm, and from bowel is 10 mm. Different positions may also help with optimizing distance from surrounding critical structures [31].

Probe number and size are also important factors to consider. Smaller, multiple cryoprobes provide synergistic effects which expand the freezing and lethal zones between closely positioned probes [32]. Ideally, one probe should be used for every cubic centimeter of tumor [1].

A technique uniquely available to cryoablation probes is the use of “stick” mode available to enable the operator to distance the targeted lesion from nearby structures with the use of probe traction. The kidney is fixed via ligamentous attachments surrounding the hilum, however, no attachments exist around the capsule. As a result, the kidneys are mobile within the perinephric space. This can make penetrating the kidney difficult at times, as the kidney may move close to sensitive structures in the process of piercing the target lesion. Once the needle traverses the lesion, the probe is placed in “stick” mode. The needle is gently retracted and can be held in place with sterile folded towels placed between the needle hub and the patient (Figure 126.1).

Hydrodissection and pneumodissection are useful techniques to move adjacent viscera away from the ablation zone. We try to achieve the ideal distance of 15–20 mm from target tumor margin [5]. In both techniques, after the first ablation probe is placed and set to “stick,” a second needle is utilized to inject either air and/or saline or dilute contrast in an effort to displace the nontarget tissues from the ablation zone. Pneumodissection, or injection of air, is the preferred dissection medium, as it provides [33] spatial isolation and better thermal insulation than saline from the lethal isotherms (Figures 126.2 and 126.3) [33]. The dissected air also provides a natural negative contrast on CT imaging which is usually performed without intravenous contrast administration. Some advocate the use of 2% contrast-tinted saline when performing hydrodissection to achieve a similar effect [5].

During probe placement, avoidance of the collecting system should only be a concern during puncture and needle placement. Numerous studies have demonstrated safety of inclusion of the collecting system within the zone of the iceball. As long as the collecting system is not punctured with one of the probes, appreciable urine leaks, even in cases of significant collecting system compression by the iceball on CT imaging, have not been reported [30]. Pathological studies suggest that even

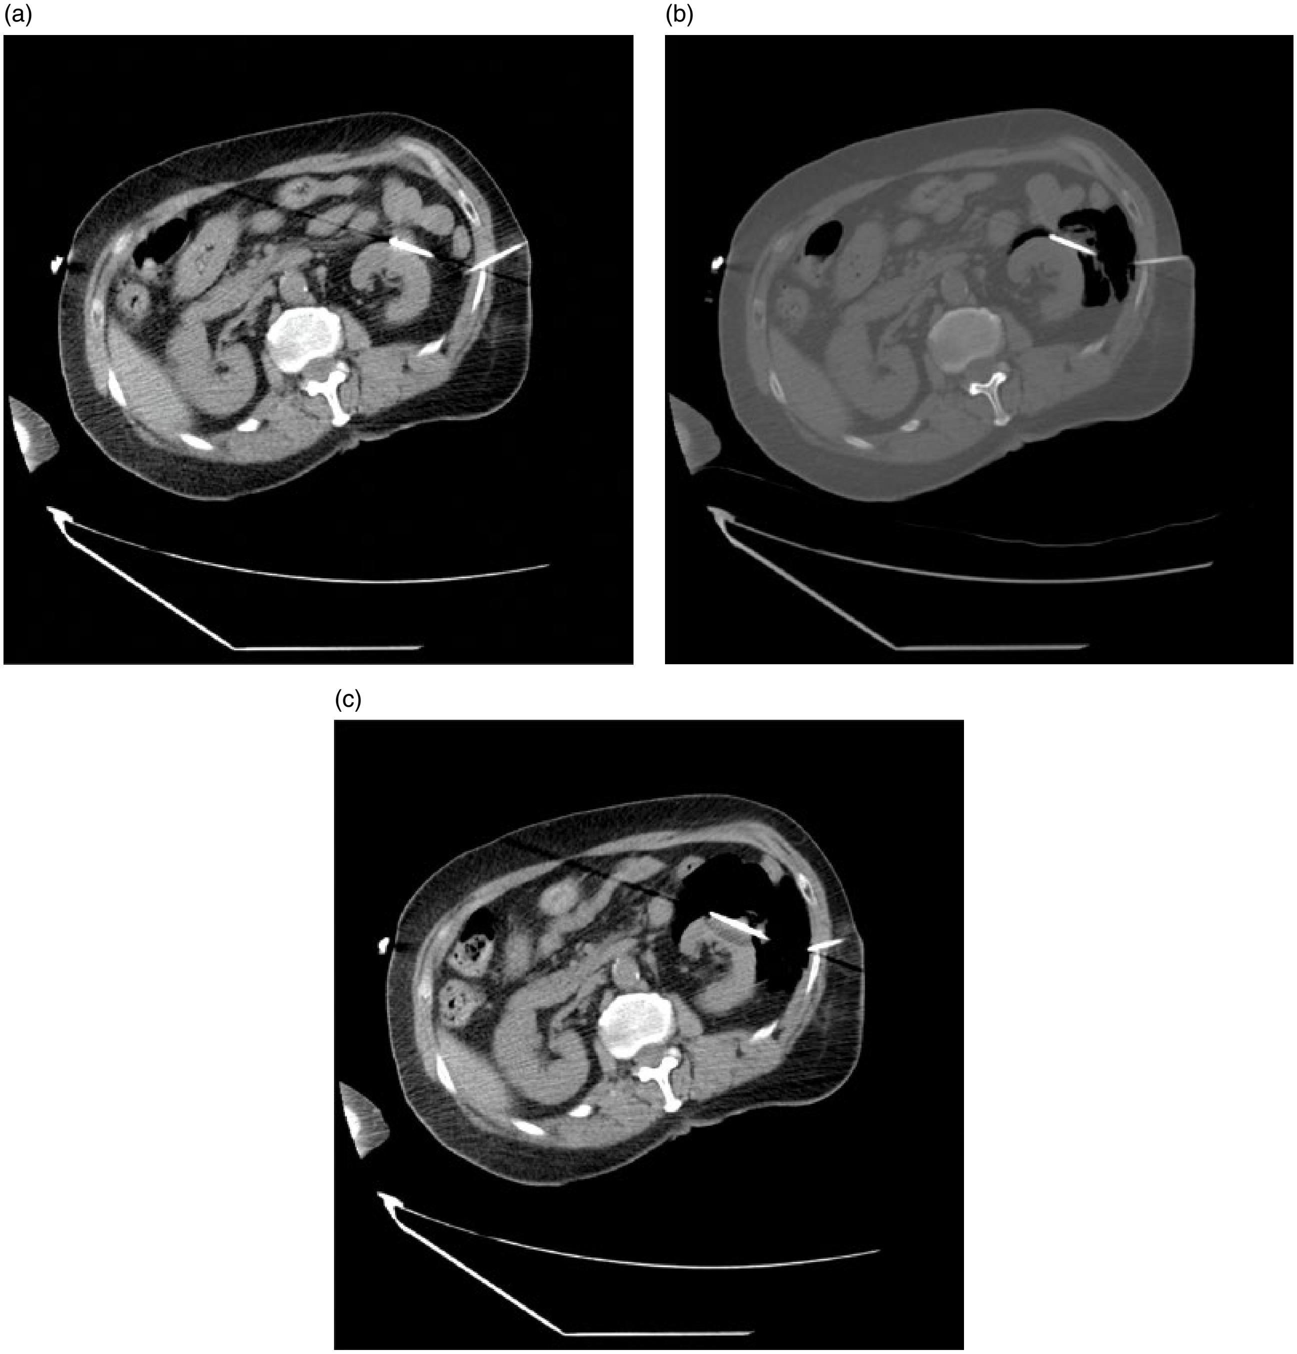

**Figure 126.1** (a) Soft tissue window: cryoprobe traversing lesion. Second needle partially visible, with tip in periephric space. (b) Bone window same level. (c) Bone window: mid-ablation. Layer of air provides distance and thermal insulation ot the adjacent bowel. Hypodense freezing zone is visible.

where partial necrosis is noted in the renal pelvis, structural integrity is preserved, suggesting relative resistance to cryotherapy [5, 7, 12, 34].

Successful ablation rests upon proper monitoring of ablation, rapid cooling, slow thawing, and repetition of the freeze–thaw cycle [7]. A temperature of −40 °C to −50 °C is thought to be required for absolute lethality during a single cycle, but −20 °C to −40 °C has been shown to be sufficient for most solid parenchymal tumors [7]. A distance from the outer margin of iceball to kill zone of 6 mm was demonstrated in animal models [7]. In practice, the targeted iceball should ideally extend at least 5–10 mm past the edge of the tumor [29].

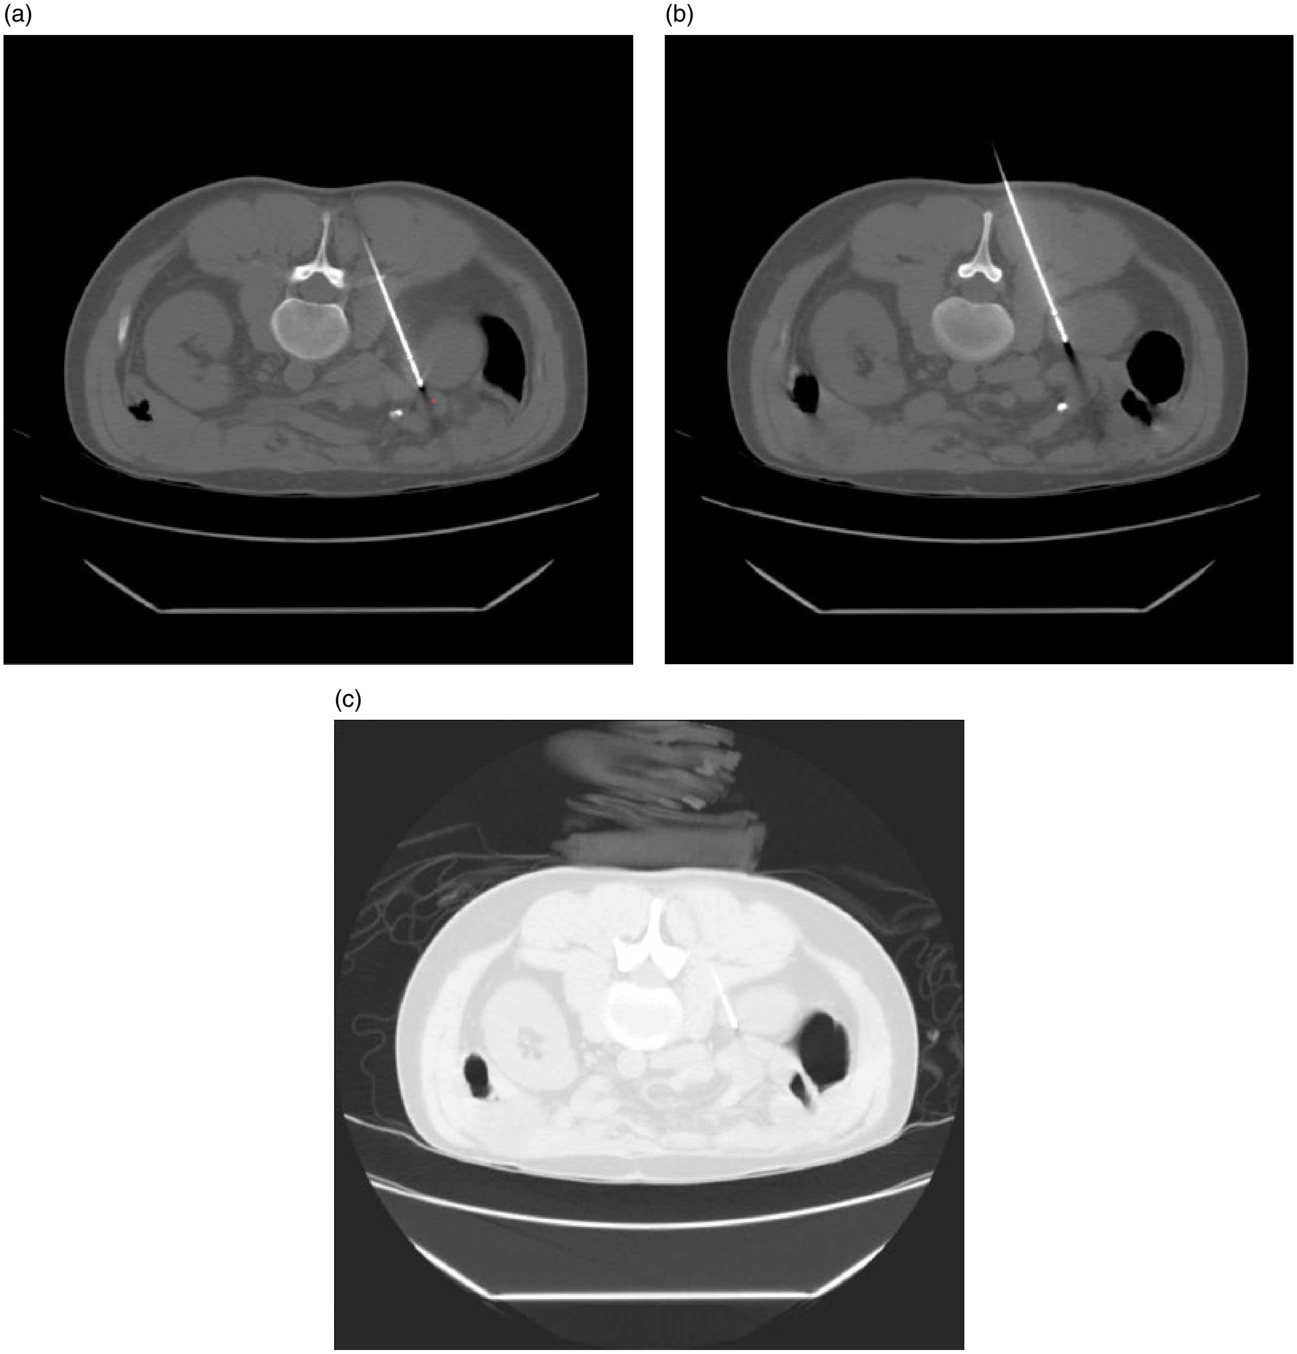

**Figure 126.2** Traction technique. (a) Bone window: cryoprobe traversing exophytic right renal lesion. Notice adjacent duodenum (red asterisk). (b) Using probe in stick mode, the lesion and kidney have been safely retracted away from the bowel. (c) Lung window: adjacent slice demonstrates a stack of towels placed in succession to safely distance the probe kill zone from vulnerable structures.

Some authors vary the length of freeze cycles according to tumor size, ranging from 3 to 12 minutes [30]. Other authors have discussed the use of active versus passive thawing between the two cycles. At our institution a 10-minute active freeze is used for both first and second cycles, with an active intervening thaw cycle [7, 29, 30]. We also recommend a review of intermittent CT to demonstrate iceball progression at approximately 4 and 9 minutes of each freeze cycle [30].

In the immediate postprocedure period, a completion CT is performed to check for bleeding [29]. Postprocedure evaluation of patients should focus on pain, vital signs, and evidence of hematuria on urination. After a brief period of observation, patients are instructed to resume

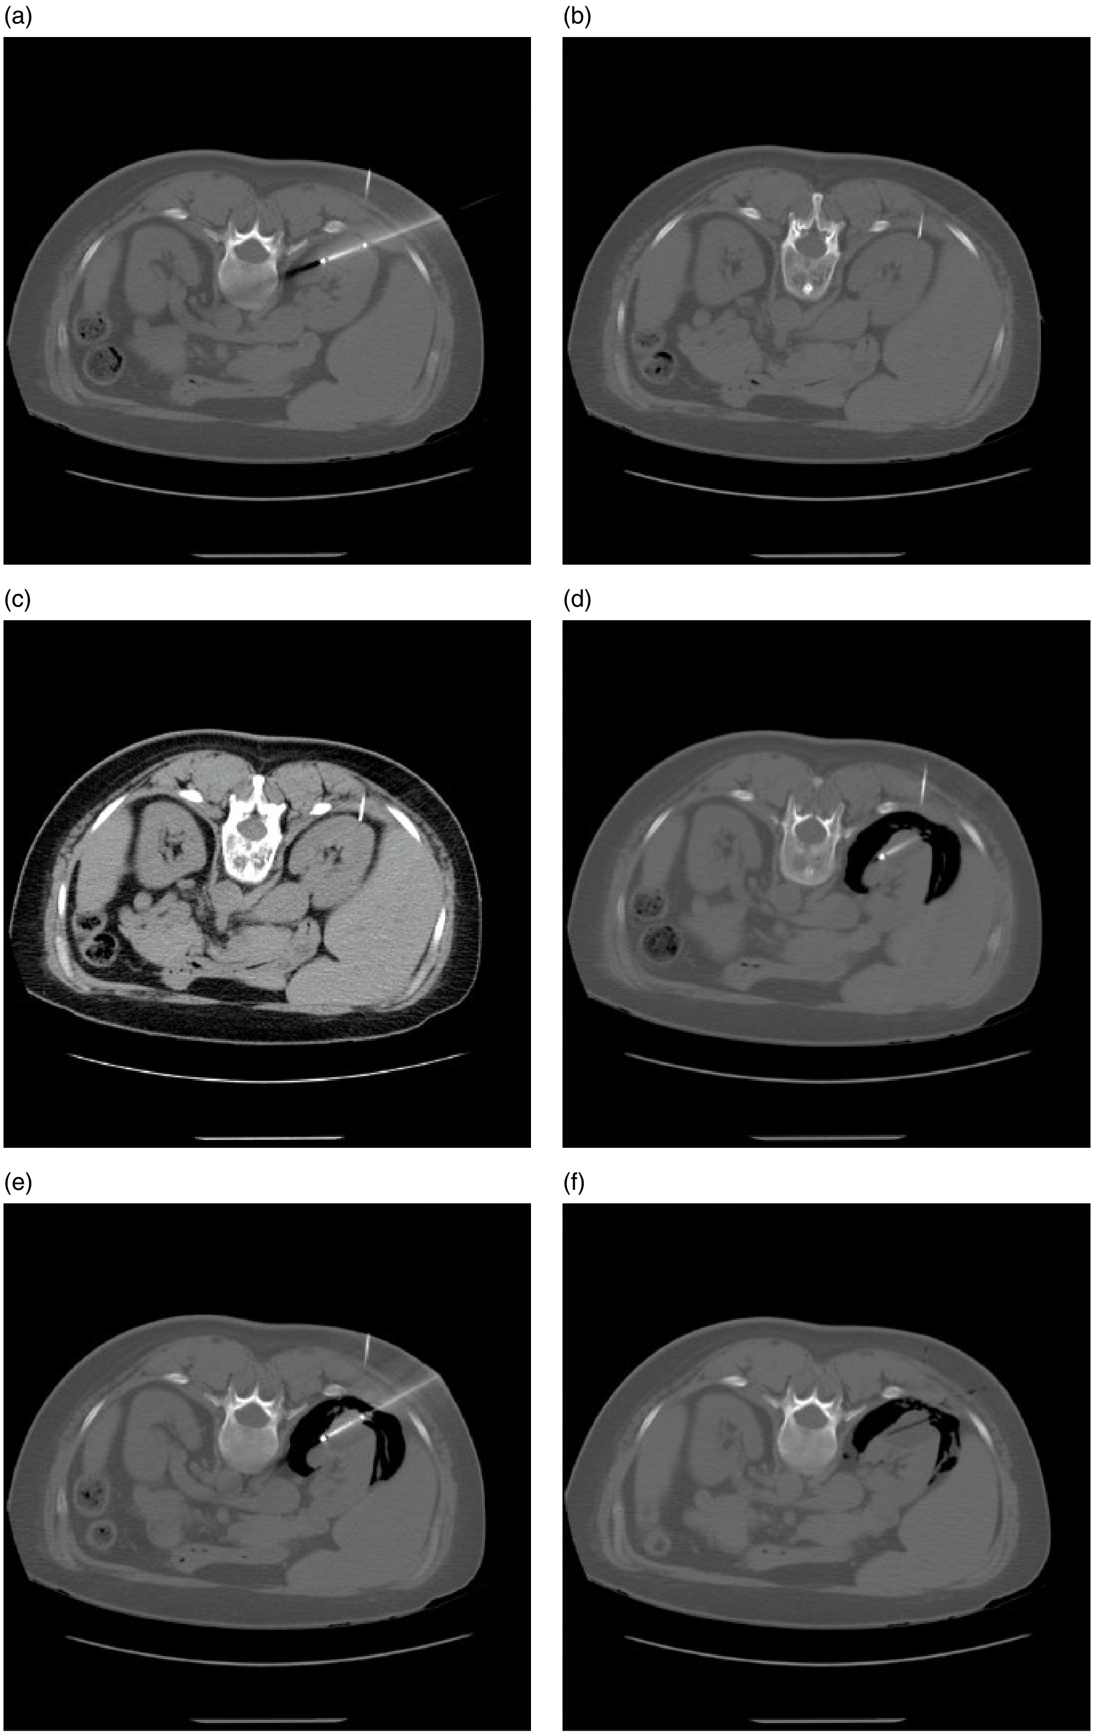

**Figure 126.3** Pneumodissection. (a) Bone window: cryoprobe traversing lesion. (b) Adjacent slice: an additional needle is placed at the renal capsule. (c) Soft tissue window: same level as (b). Air is subsequently insufflated. (d) Bone window: mid-ablation. Layer of air provides distance and thermal insulation to the adjacent diaphragm and abdominal wall, as well as the major nerves traversing the retroperitoneal space, the iliohypogastric, ilioinguinal, and genitofemoral nerves. A hypodense freezing zone is visible. (e) Adjacent slice. (f) Probe has been removed. Air is not evacuated.

activities, and then are discharged home [30]. Evidence of significant hematuria or pain warrants further observation, and in some cases, repeat imaging and admission [30]. Adverse outcomes of pneumothorax, flank paresthesias, and, in rare cases, urinary sepsis, have been reported. Small, self-limited pneumothoraces comprise the largest cohort of adverse immediate outcomes [5].

### Laparoscopic techniques

Cryoablation can be performed both percutaneously or intraoperatively via a laparoscopic approach. Studies have examined the relative efficacy and safety profiles of these two approaches. Although some have argued that laparoscopic approaches offer easier access to anteriorly located tumors, the percutaneous approach has been demonstrated to be safer than open or laparoscopic techniques and equally effective [28]. Similar oncologic outcomes have been repeatedly demonstrated between laparoscopic cryoablation (LCA) and percutaneous cryoablation (PCA) [29]. Percutaneous ablation also has the added benefits of shorter hospital stay, lower complication rates, and reduced overall cost [7]. The authors advocate for the use of a percutaneous approach for almost all renal cryotherapy, and feel that in most cases, if laparoscopy is undertaken, there should be no reason not to perform partial nephrectomy with its validated benefits.

## Outcomes

### Post-therapy monitoring

Evaluation of procedural success of cryoablation is based on intravenous contrast-enhanced CT or MR imaging, for which a number of follow-up protocols have been described [28]. A completion noncontrast CT performed immediately after the procedure is generally preferred for evaluating for immediate postprocedure complications. Following this, postprocedure contrast-enhanced MRI is generally considered a reliable method for screening for recurrence [1]. Three-month follow-ups are generally reserved for cases where there is concern for incomplete or inadequate treatment, with any distinct or nodular enhancement in the ablation bed representing incomplete treatment [5]. Surveillance is otherwise recommended at 6, 12, and 18 months, then annually, or at the discretion of the clinician for at least 5 years [5]. In subsequent examinations, nodular tumor enhancement is the hallmark of recurrence [29].

### Performance of cryoablation

Success of cryoablation has been encouraging. Overall 5-year survival numbers have been reported at 97% and cancer-specific survival 100%, comparable to partial nephrectomy [7]. Not all operators enjoy the same results, and studies suggest operator-specific and patient-specific factors which may affect outcomes. For example, a demonstrable operator experience effect has been observed, although in most cases this affects technical success, rather than safety of the procedure [5].

### Patent-specific factors

Tumor size has been cited as a factor influencing the success of cryoablation, with authors reporting an increase in recurrence following PCA in tumors greater than 3 or 4 cm [35, 36]. Location of tumor is also a factor in treatment success, with anterior tumors more likely to demonstrate recurrence [36].

Although not directly linked to treatment failure, other intrinsic factors which affect probe placement may impact the overall likelihood of successful cryoablation. Body mass index, for example can decrease quality of real-time CT imaging, potentially leading to decreased accuracy and operator confidence in probe placement [29].

## Conclusions

The continually evolving patterns of the diagnosis of renal tumors have accompanied an increasing need for minimally invasive therapies. Patients who cannot tolerate surgery or require nephron-sparing therapies with the proper size and tumor configuration can benefit from cryoablation. Cryoablation also offers factors which confer unique advantages over other ablative technologies and therefore, with time, will probably achieve widespread adoption for small, optimally positioned tumors in all patients. Given the economic and patient-related factors, as well as the safety profile and technical success rates, renal cryoablation continues to grow in importance as a modality for the treatment of renal masses.

## Varicocele

### Introduction/epidemiology

Testicular varicocele is a common condition of pampiniform plexus which is usually asymptomatic but may result in severe pain, discomfort, subfertility, and/or physical deformity. The incidence of testicular varicocele has been reported in as many as 23% of the normal healthy male population. Rates as high as 42% have been reported in the elderly population, suggesting a correlation with age [1]. A subset of patients (i.e. nutcracker syndrome, discussed later) may present with hematuria and links to subfertility have been reported as far back as the 1800s [2]. The etiology of the subfertility appears to be related to the quality of the semen, which is dependent on testosterone production [1, 2].

Varicoceles are predominantly unilateral, with the majority of cases occurring on the left side due to venous drainage anatomy (see later). Bilateral varicoceles are present in a subset of patients; however, the incidence is debated in the literature and has been reported to be as high as 80% when diagnosed with imaging [2]. Along with improvement in diagnostics, many treatment options have also emerged to treat these patients, with a trend toward less-invasive procedures. Herein, we describe the clinical presentation, imaging manifestations, treatment indications, and treatment options, with a focus on gonadal vein embolization.

### Etiology/anatomy/pathophysiology

The pampiniform plexus consists of three spermatic vein tributaries with interspersed anastomoses resulting in collateral circulation between the anterior, middle, and posterior pampiniform plexuses. Varicoceles result from a reversal of blood flow in the gonadal veins that drain the pampiniform plexus. Etiologies of primary or idiopathic varicocele appear to be multifactorial [1, 2]. Primary varicocele occur more commonly on the left as the left gonadal vein drains into the left renal vein (LRV) as opposed to directly into the inferior vena cava (IVC), as it does on the right. The left gonadal vein is thus longer than the right gonadal vein and makes an acute angle as it drains into the LRV. The increased LRV pressure, compared with the IVC, results in retrograde flow into the left gonadal vein. “Nutcracker phenomenon” or compression of the LRV as it traverses between the aorta and the superior mesenteric artery (SMA) is a common etiology of a primary varicocele [2]. Venous valves are present in 90% of patients; they are usually located at the junction of the gonadal vein and its draining vein (i.e. renal vein on the left and IVC on the right). Congenital absence of venous valves or valvular incompetence predispose patients to reflux and thus varicoceles [1].

Secondary varicoceles occur from extrinsic pathologic compression of the LRV or draining spermatic vein, most commonly abdominopelvic malignancies. Nonmalignant masses such as hydroureter and abdominal aortic aneurysms are also sources of compression. A rare cause of varicocele formation is a splenorenal shunt which may form in patients with portal hypertension. Accordingly, clinical examination and radiologic evaluation (detailed later) are crucial in the initial consultation of a patient presenting with varicocele to identify treatable secondary causes as treatment would be considerably different.

### Patient evaluation and selection

Preprocedural evaluation is imperative in patients who present with symptoms consistent with varicocele. A focused but detailed history must be obtained to rule out

*Smith’s Textbook of Endourology*, Fourth Edition. Edited by Arthur D. Smith, Glenn M. Preminger, Louis R. Kavoussi, and Gopal H. Badlani.

Companion website: www.wiley.com/go/smith/textbookofendourology

other causes of testicular pain and subfertility [2]. For example, patients with abdominal malignancies may present with abdominal pain or symptoms of mass compression (i.e. urinary or bowel obstruction). Patients with anemia or hypercoagulable states may declare malignancy on blood tests. As mentioned earlier, patients with nutcracker syndrome may present with hematuria, either macroscopic or microscopic on urinalysis. Patients with splenorenal shunts may present with signs and symptoms of portal hypertension.

Semen analysis should be obtained not only to confirm etiology of patients presenting for subfertility but also to gauge results post treatment. Physical examination is also important as it may elucidate alternate diagnoses for patients with secondary varicoceles. Classic physical examination finding includes a "bag of worms" scrotum. Patients should be examined in both the supine and standing positions. The supine position may reveal alternate diagnoses such as intrascrotal neoplasm or infection. Furthermore, varicoceles that do not resolve while lying supine may be secondary to an underlying cause (i.e. neoplasm). Varicoceles declare themselves in the standing position due to the effects of gravity on venous flow and may be accentuated by Valsava (Figure 127.1). A grading system based on physical examination findings is detailed in Table 127.1 [1, 2].

Radiologic evaluation of presumed testicular varicocele should begin with ultrasound using a high-frequency, high-resolution 7–10 MHz linear transducer performed in the standing position. As with history and physical examination, testicular ultrasound can help identify alternate diagnoses, especially in cases where a varicocele is not seen or palpated. Diameters of dilated vessels in the pampiniform plexus and the main draining vein can be measured (normal: up to 2 mm) [1]. Grayscale ultrasound should be accompanied with duplex imaging (color and pulsed). These techniques allow for real-time visualization of reflux into the pampiniform plexus, especially with Valsalva, which increases sensitivity and specificity (up to 95%). Multiple scoring systems have been developed to determine the presence of a varicocele on color Doppler ultrasound, the most commonly used being the Sarteschi's classification (Table 127.2) [3, 4]. Testicular ultrasound volume must be measured in children because testicular growth (usually of the left testicle) is affected by varicocele. Return of normal testicular development following treatment is achieved in up to 80% of patients [4].

Patients in whom a primary varicocele is diagnosed and have pain or subfertility issues should be referred for treatment. Large (grade III) varicoceles that cause cosmetic issues may also be considered for treatment. Patients with isolated right-sided varicoceles, bilateral varicoceles, or varicoceles that do not reduce with change in position (standing to supine) or do not demonstrate increase with Valsalva require further workup. A contrast-enhanced computed tomography (CT) or magnetic resonance imaging (MRI) scan of the abdomen and pelvis should be obtained to exclude malignant and benign masses causing obstruction. Furthermore, cross-sectional imaging may be of value in cases where

there is atypical anatomy. For example, there are many congenital variations of the left and right spermatic veins, especially in cases of urogenital sinus and renal anomalies, which often occur together [2]. A wide range of pelvic anastomoses with pelvic veins must be identified to prevent persistence or recurrence of varicoceles (i.e. retroperitoneal, lumbar, iliac veins, etc. Figure 127.2a) [5]. These variations may present a dilemma to the interventional radiologist when attempting to treat the patient. Cross-sectional imaging for the evaluation of the varicose veins is detailed in the next section in patients with pelvic congestion syndrome.

Surgical options to treat varicoceles include open varicocelectomy, laparoscopic varicocelectomy, and microsurgical subinguinal varicocelectomy. Open varicocelectomy requires general or intrathecal anesthesia in order to make one of three incisions. The Palomo technique involves an open retroperitoneal approach for proximal ligation spermatic vessels. Smaller incisions using a low inguinal or subinguinal approach have been developed. Laparoscopic varicocelectomy also requires general anesthesia and utilizes a transperitoneal approach. Microsurgical subinguinal varicocelectomy is a less-invasive alternative to open and laparoscopic techniques that does not involve the abdominal fascia or musculature but still allows for identification of anatomy (including adjacent arteries) and can be performed under local anesthesia [2]. The first endovascular treatment of a varicocele dates back to 1978 [1]. Since then, advances in imaging and techniques have allowed for successful of gonadal vein embolization. Furthermore, radiation exposure is concerning for the pediatric population [6]. Gonad shielding and collimation is thus crucial. Accordingly, a multidisciplinary approach among interventional radiology, urology, and reproductive medicine should be undertaken to care for these patients.

## Interventional treatments

Percutaneous and endovascular treatments of varicoceles can be performed in the outpatient setting. The procedures can be performed under local and/or minimal intravenous sedation using midazolam and fentanyl. Appropriate monitoring equipment and staff are of course necessary. Appropriate shielding techniques must also be available to minimize radiation exposure to the gonads. For patients with iodinated contrast allergies, $CO_2$ digital subtraction angiography may be utilized [1, 2, 6].

### Vascular access

For the purpose of technical detail, the future discussion will pertain to a left-sided varicocele with mentions of nuances regarding treatment of a right-sided or bilateral varicocele. After sterile preparation and local anesthesia using 1% lidocaine, vascular access is most commonly obtained via the contralateral common femoral vein (i.e. right common femoral vein for a left-sided varicocele) using fluoroscopic and/or ultrasound guidance (Figure 127.3a). The contralateral approach allows for a favorable angle to catheterize the gonadal vein from the LRV. In addition, access to the right gonadal vein may be easier from a jugular or brachial vein approach due to a straighter course as its origin makes an acute angle immediately from the right anterolateral aspect of the IVC (Figure 127.3b) [6]. A short vascular 4 or 5 Fr (outer inner diameter) sheath is exchanged over a 0.035-inch guidewire (most commonly, a Bentson wire; Cook Medical, Bloomington, IN, USA) using the Seldinger technique. An angled 6 Fr Pinnacle Destination guiding sheath (Terumo Interventional Systems, Somerset, NJ, USA) can be used if the operator plans to use a vascular plug. An IVC venogram is performed to identify the origin of the renal veins (Figure 127.4a). A 4 or 5 Fr catheter is than placed into the IVC over the guidewire and used to catheterize the LRV. A hydrophilic system is preferred to help prevent vasospasm [2]. The 100 cm Cobra catheter (Cook Medical, Bloomington, IN, USA) is advantageous in this setting because its curved tip allows for easy catheterization of the left gonadal vein (Figure 127.4b,c). If the left gonadal vein proves difficult to catheterize, a coaxial system with guide catheters or guide sheaths can be used to stabilize the system [6]. In cases with extreme angulation or when high torquability is required, a braid-reinforced catheter may help [2]. A reverse curve catheter (for example SOS Omni Selective Catheter) may be used to catheterize the right gonadal vein directly off the IVC (see Figure 127.6a,b). A 2.8 Fr microcatheter can be introduced coaxially into the guiding catheter to assist in catheterization of the gonadal vein to the level of the inguinal ligament to study the pampiniform plexus.

### Venography

The catheter can be advanced into the distal gonadal vein just proximal to the origin of the pampiniform plexus. Pretreatment venography of the gonadal vein is performed at the level of the ischiopubic ramus to confirm the diagnosis as well as identify the highly variable collateral venous circulation [1, 2, 6]. Variant anatomy (i.e. duplicated gonadal vein) and collateral vessels, sometimes from the internal iliac vein, must be identified (Figures 127.4d and 127.5d) and embolized to

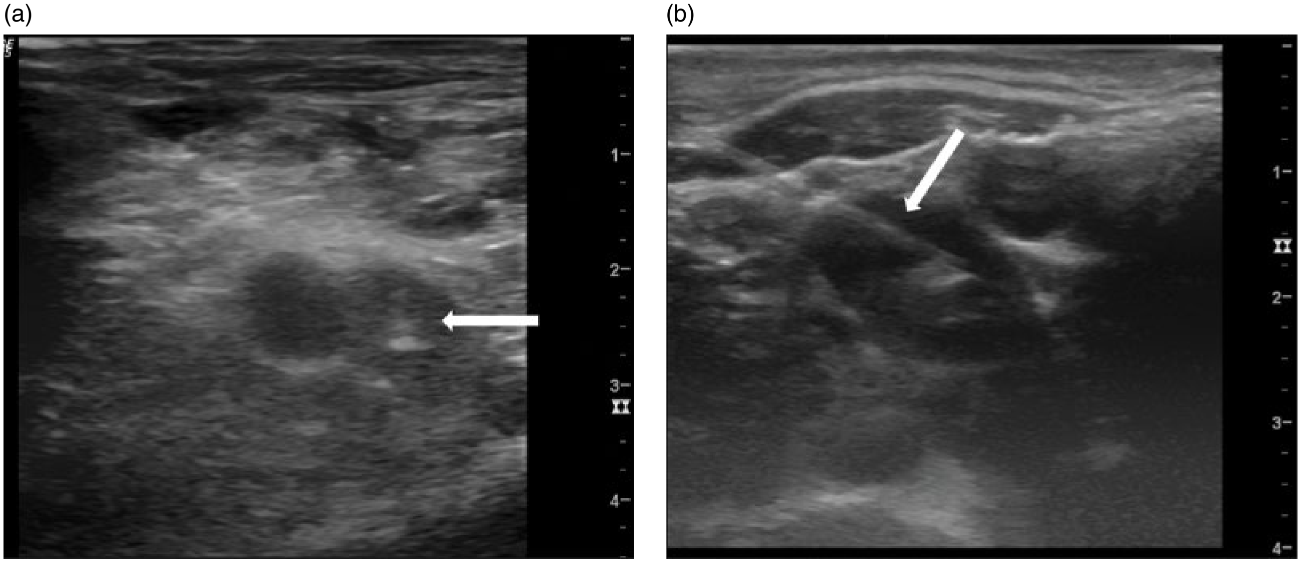

Figure 127.3 Ultrasound guided venous access. (a) Grayscale ultrasound image demonstrates a hyperechoic needle (arrow) in the lumen of the right common femoral vein and (b) the right internal jugular vein.

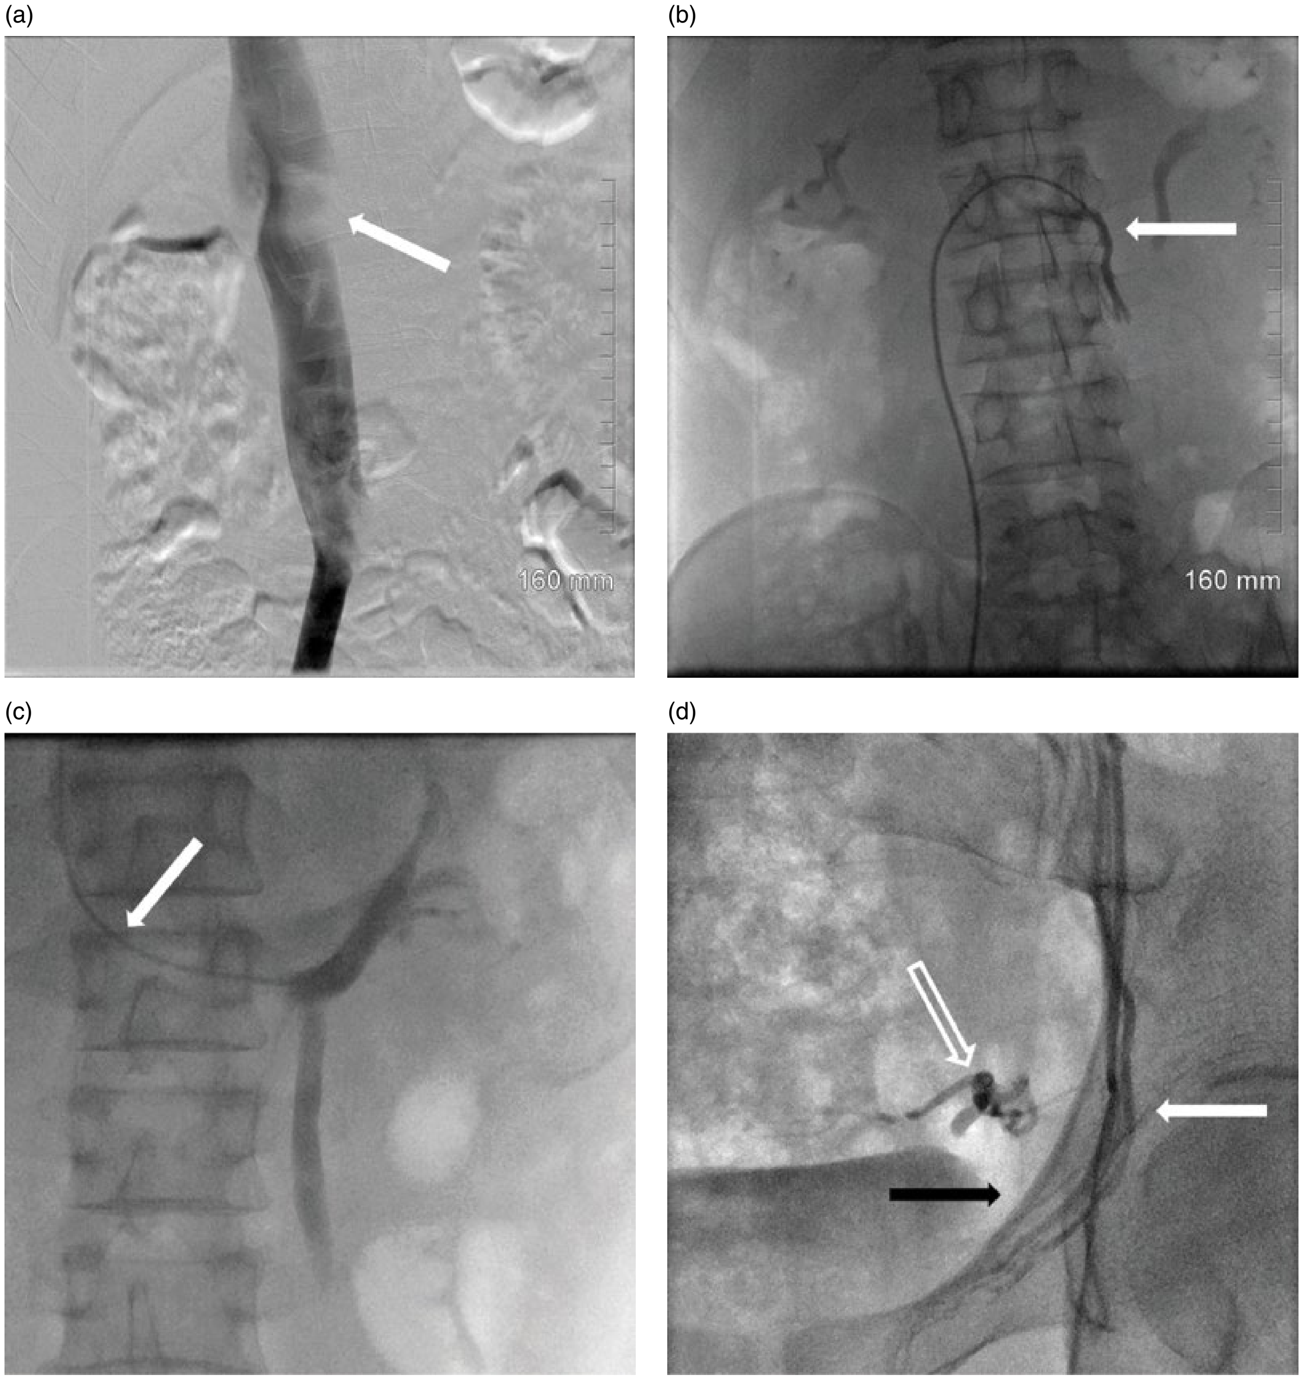

**Figure 127.4** Left gonadal vein access and venography. (a) Venography demonstrates bilateral flow voids at the level of the second lumbar vertebra (arrow showing dynamic filling defect related to inflow from the left renal vein). (b) Contrast injection of the left renal vein via a right common femoral vein approach. (c) Right internal jugular vein approach demonstrates the origin of the left gonadal vein. (d) Pretreatment left gonadal venography of the gonadal vein is performed at the level of the ischiopubic ramus (black arrow) to confirm the diagnosis as well as identify the highly variable collateral venous circulation (white arrow pointing to a parallel retroperitoneal collateral and white hollow arrow pointing to an axial medial retroperitoneal collateral).

prevent varicocele persistence or recurrence (Figure 127.5a,e). For optimal evaluation of the varicocele, the patient can be coached to bear down during contrast injection to demonstrate venous reflux. If the patient cannot adequately bear down, he can be positioned in reverse Trendelenburg to use the assistance of gravity. The classic venous drainage pattern is the medial and lateral branching of the gonadal vein at the

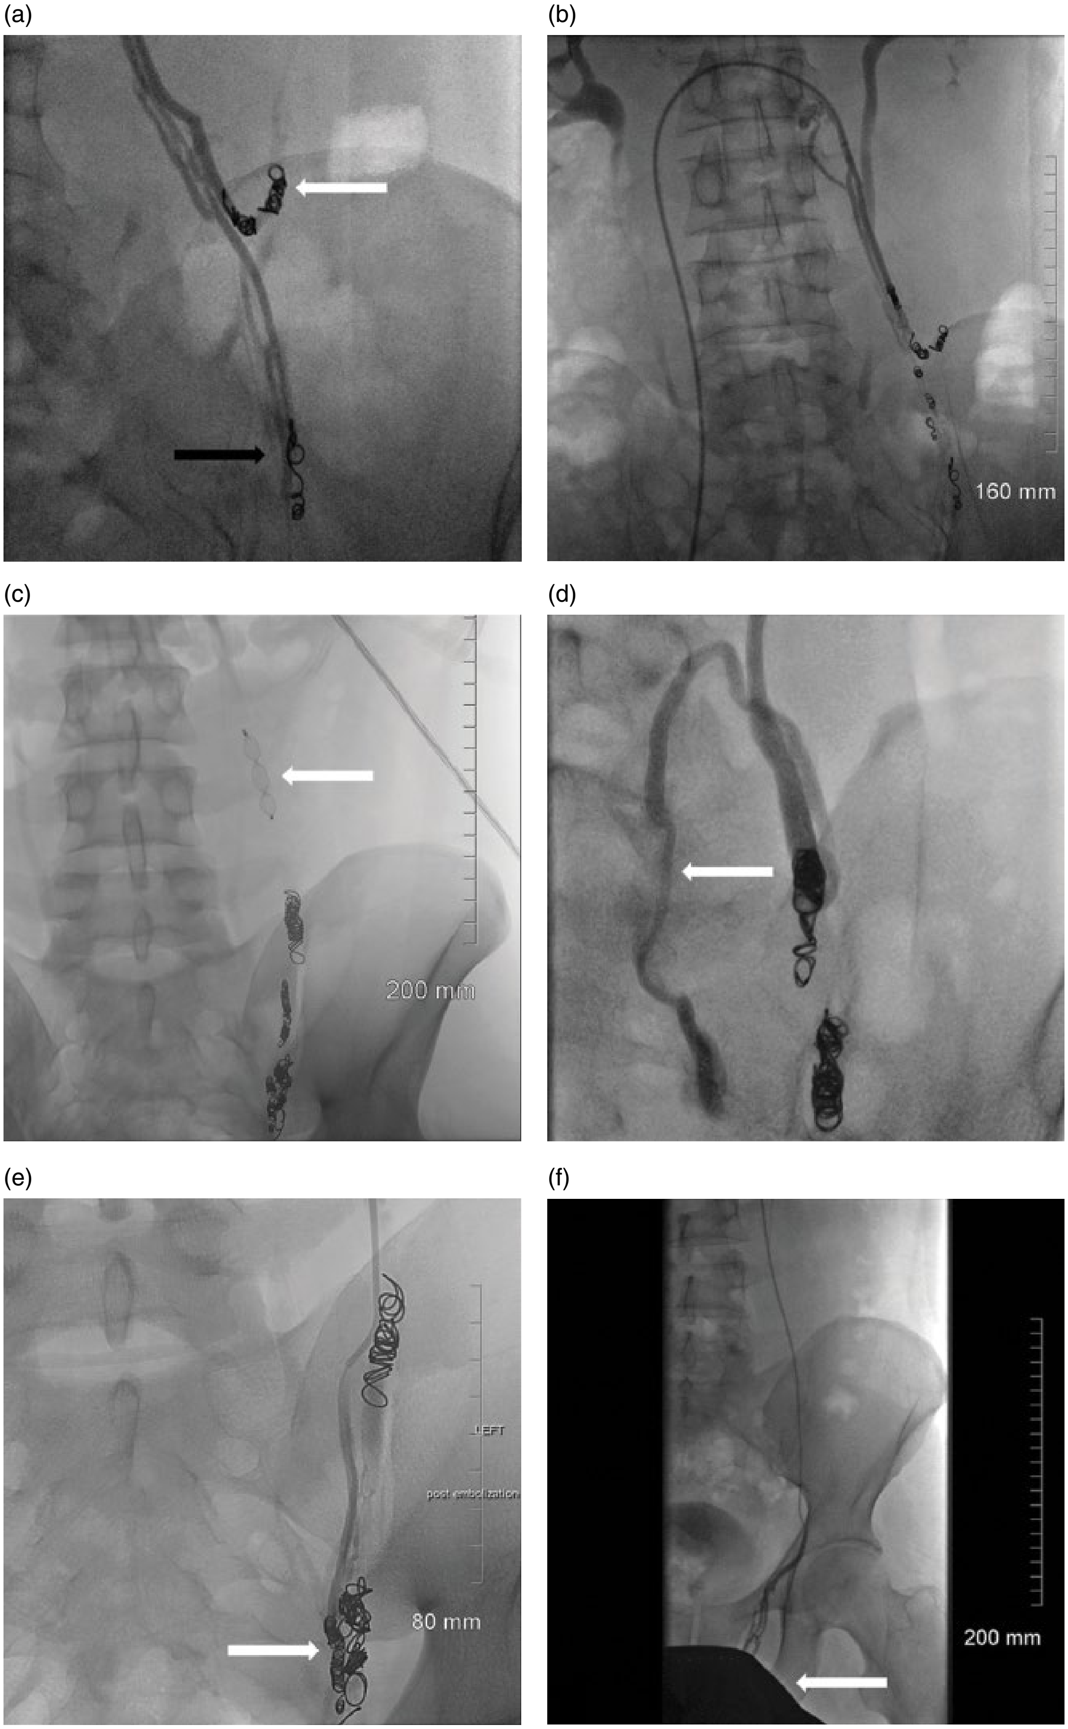

**Figure 127.5** Left gonadal vein embolization. (a) Contrast injection of the proximal left gonadal vein after coil embolization of the distal gonadal vein (black arrow) near the level of the pubic symphysis; below the level of the lowest axial lateral retroperitoneal collateral (white arrow). (b) Contrast injection of the proximal left gonadal vein after multilevel coil embolization of the gonadal vein. (c) Proximal gonadal vein embolization using an AMPLATZER vascular plug (St. Jude Medical, St. Paul, MN, USA) in a different patient. (d) Contrast injection of the left gonadal vein after coil embolization of the distal gonadal vein (black arrow) in a different patient demonstrating a medial parallel retroperitoneal vein which was subsequently (e) embolized with coils. (f) Radiation protection via gonadal shielding and collimation. Arrow points to gonadal shield used to protect the gonads from fluoroscopic radiation.

level of L4 [1]. If the plan is to use a sclerosant, subsequent small-volume contrast injection into the anterior pampiniform plexus is performed with Valsalva in the reverse Trendelenburg position while maintaining external pressure on the spermatic cord, either by hand or with a rubber band [1, 7]. This is to ensure that no reflux is seen into the posterior pampiniform plexus into the main draining gonadal vein. Careful manipulation of the catheter and wire is recommended as vasospasm and venous perforation may occur. Vasospasm tends to occur more frequently in children. A 0.016 inch guidewire and microcatheter system may be of assistance with technically difficult (i.e. tortuous) anatomy or to cross a perforated segment [1, 2]. In cases of persistent or large extravasation, the procedure should be terminated and rescheduled. Nitroglycerin (100–500 μg, dosed based on the patient's blood pressure) may be given through the catheter in cases of severe spasm [2, 7].

### Sclerotherapy

If no reflux is observed on contrast injection into the anterior pampiniform plexus or draining gonadal vein, the operator may proceed with injection of sclerosant with Valsalva in the reverse Trendelenburg position and external compression of the spermatic cord just as in the test bolus contrast injection [2]. While there are many different sclerosing agents that induce endothelial injury secondary to a thermochemical reaction, sclerosis is most commonly performed using a dilution of 3% Na-tetradecyl-sulfate (STS) [1]. Different dilutions have been reported to be effective; for example, a mixture 2–6 ml of STS and air in a 1:4 ratio is typically used to create a foam using the Tessari technique with a three-way stopcock [1, 7]. A small amount of contrast may be added to the mixture for visualization. Pressure on the spermatic cord can be released 1 minute after injection. If reflux is seen into the posterior pampiniform plexus or draining gonadal vein, additional sclerosant can be injected. Balloon occlusion catheters are used in cases of large draining gonadal veins or in cases of bidirectional flow [2]. After reflux ceases, gentle contrast injection into the gonadal vein is performed to confirm occlusion. When complete occlusion is obtained, results are considered to be equivalent to surgical ligation. An anterograde percutaneous sclerotherapy technique was employed in the early years of varicocele embolization. However, catheterizing the gonadal vein proved difficult due to complex anatomical variations. For this technique, an inguinal or subinguinal incision is made to isolate and access the pampiniform plexus. Anterograde venography is performed and sclerosis is performed as mentioned earlier.

### Gonadal vein embolization

Venous embolization involves occlusion of the draining gonadal vein and thus preventing reflux into the pampiniform plexus. Multiple embolic agents are available to the interventionalist. Coils are the most common embolic agents used for gonadal vein embolization. Fibered coils are surrounded by a thrombogenic fiber that facilitates occlusion of the gonadal vein, whereas hydrogel-coated coils expand to physically occlude the lumen. Detachable coils, with either mechanical or electrical detachment mechanisms, have a decreased rate of migration and vessel injury when compared to pushable stainless-steel coils, at the expense of added cost. Microcoils may be used if a microcatheter system is required to cannulate the target vessel. New detachable coils allow for accurate positioning of these embolic agents and thus increase the safety profile associated with venous embolization. The coils can be retracted into the catheter if inappropriately positioned/sized by the operator or result in venous perforation. Moreover, they also allow for a more distal occlusion [1, 2]. Embolization should begin below the lowest collateral vessel, which most commonly occurs near the level of the pubic symphysis (Figure 127.5a,d) to ensure no alternate circulation to provide flow to the distal refluxing gonadal vein (i.e. prevent persistence or recurrence) [1]. The catheter (or microcatheter) is then retracted proximally toward the draining renal vein (or IVC on the right) and multiple additional levels of embolization are performed (most commonly 3 or 4 levels) (Figures 127.5b and 127.6c). The gonadal vein should be measured at each level prior to embolization on the postprocessed digital subtraction venogram to determine coil size selection. AMPLATZER vascular plugs (St. Jude Medical, St. Paul, MN, USA, Figure 127.5c) have recently gained interest in the proximal gonadal vein as they offer a quicker alternative to coil embolization. Both coils and plugs are MRI compatible. Other uncommon options include detachable balloons and microvascular plugs [6]. Gonadal vein embolization is sometimes performed in conjunction with sclerotherapy. The sclerosant is delivered after the first (lowest) level of coils are placed. This so-called "sandwich technique" prevents reflux into the pampiniform plexus. The sclerosant can help occlude small tributaries which are too small to catheterize and may help in preventing recurrence [1].

*N*-Butyl cyanoacrylate (nBCA) glue is a liquid embolic agent that has been used for gonadal vein embolization. Glue as the embolic agent for varicocele embolization may be considered favorable in cases of recurrent or persistent varicocele to occlude small collateral veins. The ratio of nBCA to lipiodol is used to alter the polymerization rate of the glue and is determined by the capacity

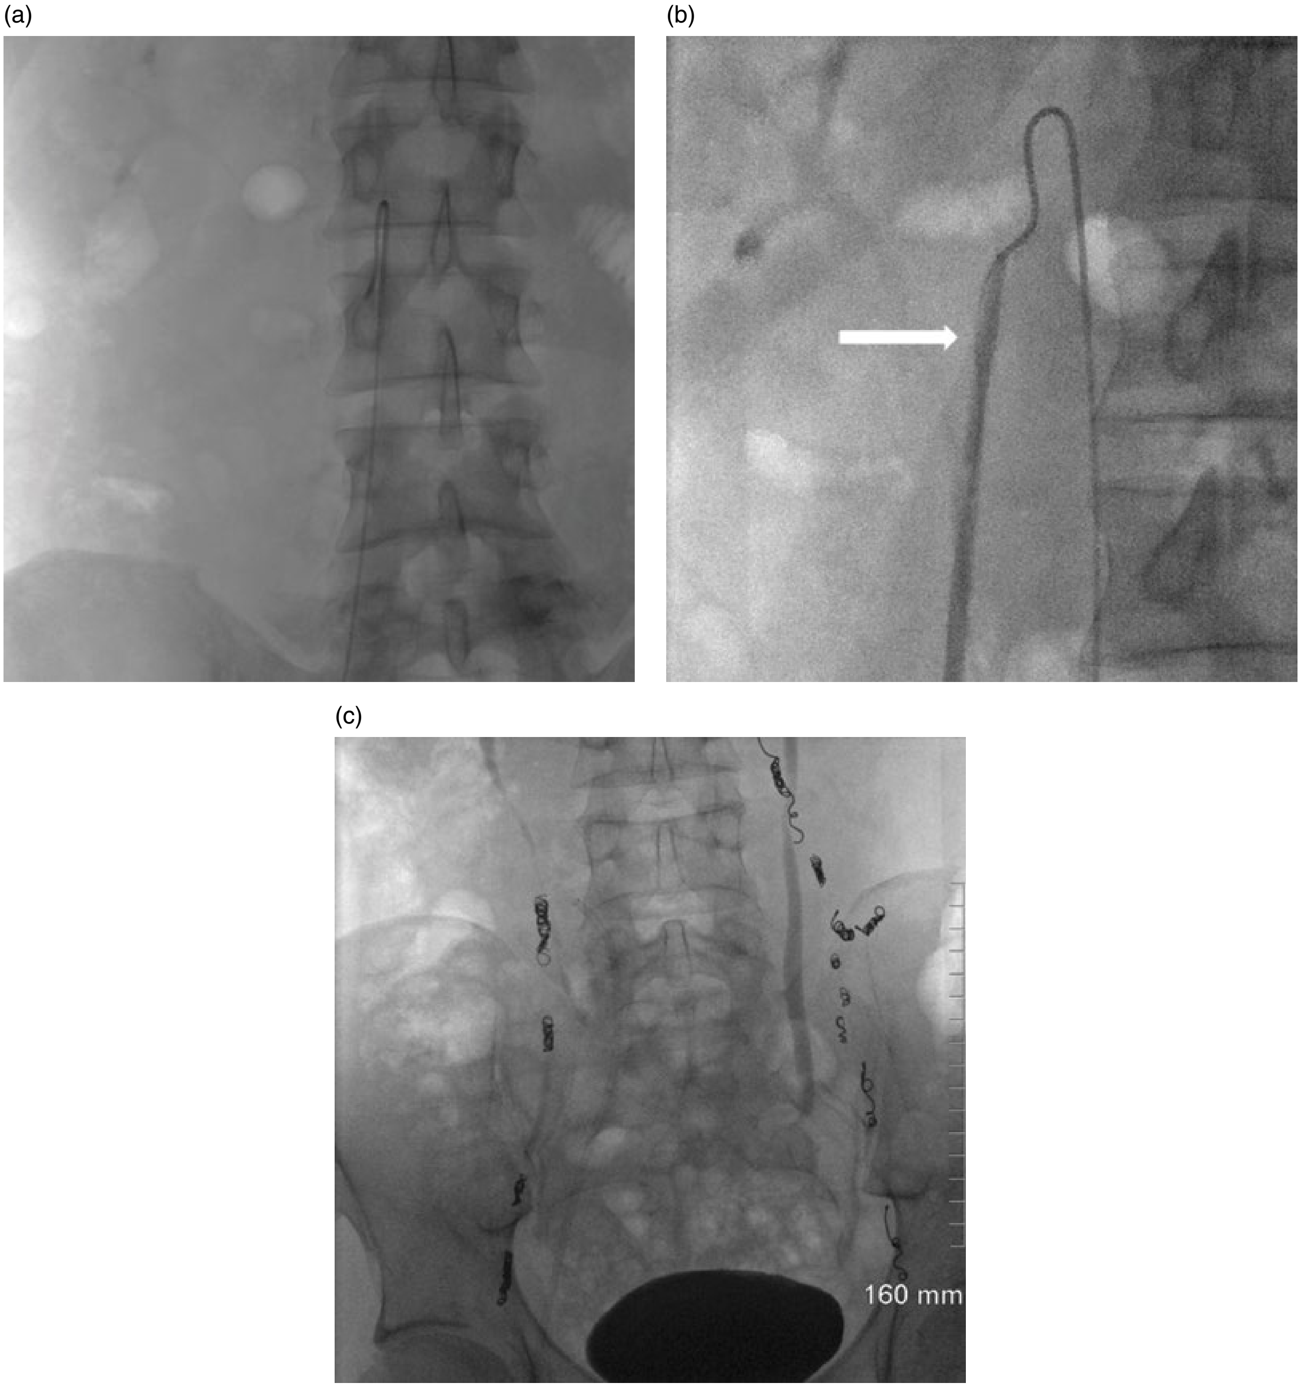

**Figure 127.6** Right/bilateral gonadal vein embolization. and flow rate of the target vessel. It is especially difficult in venous embolization because there is a higher risk of gluing your catheter to the body due to the direction of flow. Operator experience with glue is necessary due to subtleties in the technique for glue delivery. For example, a coaxial microcatheter system is necessary for the delivery of glue. The glue must be delivered slowly and at a constant rate. An additional syringe of nonionic flushes (i.e. 10% dextrose) should be connected to the glue mixture via a three-way stopcock and should be delivered before, during, and after glue delivery. This prevents premature polymerization of the glue and thus occlusion

of the microcatheter, reflux into the main catheter resulting in its occlusion, and gluing of the microcatheter or the system to the vein. The tip of the main catheter and delivery microcatheter can be soaked in silicone oil to also prevent sticking to the glue [2]. Detachable-tip microcatheters exist but are currently cost prohibitive for this purpose.

## Outcomes/complications

Technical success for gonadal vein embolization has been reported up to 96% with experienced operators [1]. However, many series have shown high technical failure rates with right-sided varicoceles [6]. A large meta-analysis demonstrated technical failure rate to be around 13% without attention to laterality [8]. Patients are generally discharged the same day with pain medications (i.e. anti-inflammatories) and a short course of oral antibiotic therapy (for example, 5 days of 1 g amoxicillin daily) [7]. Follow-up should occur in the clinic 1–2 weeks after the procedure to evaluate patients for symptom relief and complications. Nearly all patients that present with pain have resolution of symptoms within weeks. Patients receive ultrasound follow-up after three months and 1 year as well. Semen analyses can be repeated three months post procedure to follow up for subfertility.

Until recently, the jury was out in the success of gonadal vein embolization for the treatment of infertile secondary to varicocele. Recent literature suggests that the treatment not only improves semen analysis but increases pregnancy rates to nearly 50% within 3 years [9]. These findings are comparable to its more invasive surgical counterparts, including microsurgical subinguinal varicocelectomy [10]. Major complications including but not limited to nontarget embolization (regardless of complex collateral circulation), embolic migration, and/or renal vein thrombosis are rare [6]. Although gonadal vein perforation is common (Figure 127.7), it rarely leads to clinical sequelae. Postprocedure scrotal pain has been reported in many patients, especially with the use of sclerotherapy. A small subset of these patients may experience chronic pain. Epididymitis, scrotal hydrocele, and scrotal hematoma have also been reported. The minimally invasive nature of the procedure makes complications rare when compared to their surgical counterparts, which are similar to microsurgical subinguinal varicocelectomy; in contrast, complications have been reported to be as high as 30% with open and laparoscopic varicocelectomy.

For patients with persistent or recurrent varicocele, cross-sectional imaging should be obtained to evaluate the extent of venous obstruction. Rates of recurrence are reported to be at most 10% compared to their surgical counterparts, which are reported to be as high as 17% with open and laparoscopic varicocelectomy. Low inguinal or subinguinal techniques have reported rates of recurrence as low as 2% [11]. Duplicated gonadal veins and anastomotic pathways are usually the etiology for recurrence. Cross-sectional imaging allows evaluation of previous surgical or endovascular treatments which may hinder certain approaches. For example, prior proximal gonadal vein embolization may prevent accessing the gonadal vein distally to perform further treatment. Glue may be used in such cases [2]. Low inguinal or subinguinal techniques may also be considered in these patients.

### Future directions

Testicular pain and subfertility results in significant morbidity for patients with varicocele. Multicenter randomized controlled trials are needed to assess primary outcomes related to pregnancy rates and/or live births [12].

## Pelvic congestion syndrome

### Introduction/epidemiology

Chronic pelvic pain affects a third of women and is a common presenting symptom to gynecology. Pelvic congestion syndrome (PCS) is a diagnosis of exclusion first described in 1930 in patients where an underlying cause of pelvic pain was not found [13]. Patients present with nonspecific pelvic pain and can have associated constitutional symptoms (headache, gastrointestinal and urinary symptoms, or generalized pain/weakness) that may be related to the menstrual cycle. Patients can also report dysmenorrhea and dyspareunia. The pain is generally worse with situations that increase pelvic pressure, for example with pregnancy. A subset of patients also present with visible pelvic (i.e. vulvar) and/or lower extremity varicose veins. The etiology of pelvic congestion is not well understood; however, it is thought to be analogous to varicoceles in males and thus treatment parallels varicocele embolization. Ovarian varices are found incidentally in about 10% of patients, about half of whom have symptoms related to PCS. Herein, we describe the clinical presentation, imaging manifestations, treatment indications, and discuss treatment options with a focus on ovarian vein embolization [13].

### Etiology/anatomy/pathophysiology

The etiology of PCS is thought to be related to ovarian vein reflux secondary to incompetent or absent ovarian vein valves resulting in pelvic venous engorgement. However, patients with enlarged pelvic veins and/or reflux do not necessarily have PCS [13, 14]. PCS occurs most often in multiparous women and thus mass effect on the pelvic veins from a gravid uterus appears to be contributory. Longstanding pressure on the veins results in venous hypertension, which causes valvular incompetence and retrograde flow into the ovarian veins [14]. Furthermore, the effects of progesterone during pregnancy are thought to exacerbate venous dilation due to its inherent properties as a vasodilator. PCS is also seen commonly in premenopausal women, suggesting a hormonal influence. Patients with PCS often have polycystic ovaries without manifestations of the syndrome suggesting estrogenic effects. All of these factors weaken the structural integrity of the veins, resulting in refluxing valves. Some patients may have a genetic predisposition to developing PCS [14, 15]. In summary, the pelvic pain is secondary to stretch-activated pain receptors in the veins walls, which is proportional to the extent of dilatation and reflux [14].

Anatomy plays a large role in the pathophysiology of PCS. The pampiniform venous plexus resides in the broad ligament in female patients and drains into the gonadal (ovarian) veins bilaterally. Similar to the male patient, the left gonadal vein drains into the LRV and the right gonadal vein drains directly into the IVC. Variability in anatomy is common, with different collateral circulations [14]. In contrast to the male patient, many collateral pathways exist between the right and left venous circulation (Figure 127.2b) and thus patients benefit from bilateral treatment. Although PCS occurs bilaterally, valvular incompetence is usually unilateral and more common on the left [15]. Bilateral presentation is more common than in men, but an underlying etiology must still be excluded. Pelvic malignancies, uterine fibroids, and endometriosis may be culprits for secondary PCS in the female patient. Additional etiologies include IVC thrombosis and nutcracker syndrome (discussed previously) [14]. A variant of PCS that can also present with lower extremity varicose veins includes compression or valvular incompetence of the iliac veins, most commonly on the left. When the internal iliac vein is involved in isolation, lower extremity symptoms may not be present. May–Thurner syndrome is a condition in which the left common iliac vein is compressed by the right common iliac artery. These patients may present with deep venous thrombosis (DVT). Rare congenital conditions such as vascular malformations can also result in PCS [15]. Accordingly, clinical examination and radiologic evaluation are crucial in the initial consultation of a patient presenting with PCS to ensure that an underlying diagnosis is identified, as treatment would be considerably different.

### Patient evaluation and selection

Diagnosis of PCS is usually delayed in patients as the workup for pelvic pain is extensive and PCS is usually left as a diagnosis of exclusion. Visual analog scales (VAS) are typically used to grade a patient's pain, although these scores are subjective. Only a small subset of patients present with the physical deformities of varicose veins when compared to those who present with varicocele. Patients usually present with vulvar or perineal varicosities but may present with buttock and even lower extremity varicose veins. Lower extremity varicosities tend to be in the pudendal collateral distribution and appear visible on the superomedial thigh. The preprocedure workup is therefore crucial in patients presenting with pelvic pain. The diagnosis may be hidden in the details, for example within the social history as depression and relationship problems due to dyspareunia [13]. Because of the wide variety of symptoms, patients may present to different subspecialties for initial or follow-up evaluation, which adds to the complexity of the patient's care. For example, patients may be referred directly to urology for urinary symptoms of frequency and irritation with a discordant urinalysis for presumed diagnosis of recurrent urinary tract infections. Gynecologic examination may reveal adnexal tenderness, which is reported to have a reasonable specificity; however, this may lead to alternate differential diagnoses including, but not limited to, ovarian cyst or torsion [13–15]. Interestingly, pelvic pain and adnexal tenderness have been reported to be as high as 94% sensitive and 77% specific [16].

Findings suggestive of PCS are commonly made incidentally on imaging modalities for workup of a different diagnosis. Most patients who present with pelvic pain typically undergo transabdominal ultrasound using a low-frequency, low-resolution curvilinear transducer and transvaginal ultrasound using a high-frequency transvaginal probe to evaluate the uterus and adnexa to identify other potential causes of pelvic pain (i.e. ovarian cyst). If large dilated pelvic veins are identified, color and pulsed Doppler technique should be employed to evaluate these veins (Figures 127.8a). Reflux may be identified using transvaginal ultrasound in a patient with favorable anatomy and with operator experience. These veins should be evaluated with the patients standing up and performing the Valsalva maneuver, as described in the evaluation of varicocele earlier.

As mentioned, findings consistent with PCS are generally identified incidentally on cross-sectional imaging to evaluate patients for something other than PCS. CT of the pelvis requires the administration of intravenous iodinated contrast to identify enhancement of the veins and differential the conglomerate of venous structures from a pelvic mass or lymphadenopathy [13]. The CT must be performed in a venous phase of imaging, typically with a 90–180 second delay (Figure 127.8d–f). Early imaging may opacify the arterial vasculature of the pelvis which would limit the evaluation of the veins. MRI has the benefit of no radiation (Figure 127.8b,c). While there are nuanced exceptions, veins typically appear hypointense on T1-weighted images and hyperintense on T2-weighted images; gradient echo sequences provide the highest signal [13]. Intravenous gadolinium contrast-enhanced MR venography (MRV) provides great detail of the pelvic venous anatomy [13, 14]. Velocity-encoded phase contrast (VENC) imaging is under investigation for identification of reflux [14]. However, cross-sectional imaging may underestimate the degree of venous dilatation or reflux as it must be performed in the supine position (i.e. not standing) [13, 15]. Invasive methods of diagnosis such as laparoscopy are often used to identify the cause of nonspecific pelvic pain. Although these methods prove valuable to identify alternate etiologies of pain (i.e. adhesions), diagnosis of PCS is often missed due to supine positioning and pelvic insufflation [14].

Patients with presumed primary PCS with symptoms should be referred for treatment. Ovarian vein size appears to correlate with amount of reflux and symptoms. Veins greater than 8 mm in diameter appear to have reflux and these patients present with pain [15]. However, many different classification systems exist due to the high variability of presentation and anatomy resulting in different treatment paradigms. Pelvic veins less than 4 mm in diameter are considered to be within normal limits [15]. Tortuous dilated veins measuring larger than 4–6 mm or dilated ovarian veins measuring larger than 8–10 mm are diagnostic criteria used by many for the diagnosis of PCS. Dilated myometrial veins, filling of varices, and/or polycystic ovaries may also be considered in the diagnosis [13–15]. PCS is diagnosed in 56% of patients who have polycystic ovaries [16].

Nonsurgical (i.e. medical) and surgical treatment options have been developed for the treatment of PCS. Hormone therapy using medroxyprogesterone acetate or gonadotropin-releasing hormone (GnRH) analog goserelin may be effective in a short-term period [14, 15]. Surgical options include laparoscopic ligation as well as total hysterectomy with oophorectomy [15]. Less-invasive interventional techniques described for treatment of varicocele in male patients have been employed to treat patients with PCS. The first endovascular treatment of PCS dates back to the early 1990s (27 in 1) [13]. Since then, technological advances have demonstrated favorable outcomes. A multidisciplinary approach among interventional radiology, urology, and gynecology should be taken to care for these patients.

## Interventional treatments

### Vascular access

Vascular access for the endovascular treatment of PCS is identical to that of varicocele treatment. However, dual accesses may be obtained (i.e. right common femoral

vein access to catheterize the left ovarian vein via the LRV and right internal jugular/left common femoral vein access to catheterize the right ovarian vein). A brachial vein approach may also be used for selecting the right ovarian vein [17]. Bilateral treatments are usually performed in the setting of PCS due to cross-communication between the left and right pelvic venous circulation.

### Venography

Venography is also similar to that for varicocele embolization. Internal iliac venography may also be performed in select cases, for example in patients with thigh varices. In addition to Valsalva and reverse Trendelenburg positioning, a balloon occlusion test may be performed to visualize the pelvic veins. To assess for adequate Valsalva, the patient must maintain a pressure of 20 mmHg which can be assessed using the rubber tubing of a blood pressure cuff, if necessary [16]. Contrast venography is performed though balloon occlusion catheters that prevent rapid drainage of blood and fill deep collaterals [13, 15]. If contrast injection of the LRV demonstrates reflux into an ovarian vein measuring >8 mm, the diagnosis is confirmed [16] (Figure 127.9a).

### Gonadal vein embolization/sclerotherapy

These techniques are described in detail earlier in this chapter. After the diagnosis of PCS is confirmed angiographically, the treatment catheter is placed near the ovarian venous plexus and then techniques for embolization/sclerosing aforementioned are applied. The diagnostic catheter and/or microcatheter should be placed in the ovarian vein at the level of the pelvic brim to again identify the reflux and demonstrate filling of collateral veins. As mentioned, bilateral treatments are often performed, even in the setting of unilateral pelvic varicosities as vast communications exist between the left and right circulation (Figure 127.9). Single-side embolization would result in recurrence. If the plan is to use sclerotherapy, a balloon occlusion test injection of contrast may be performed to determine the amount of sclerosant necessary. Furthermore, the injection of sclerosant may also be performed with balloon occlusion in cases with large draining veins. Anastomosis from the internal iliac to gonadal circulation also exists. Balloon occlusion tests are generally performed in these cases to identify small tributaries of the internal iliac venous circulation that feed the varices. These small vessels can be subselectively catheterized prior to sclerosing to identify potential

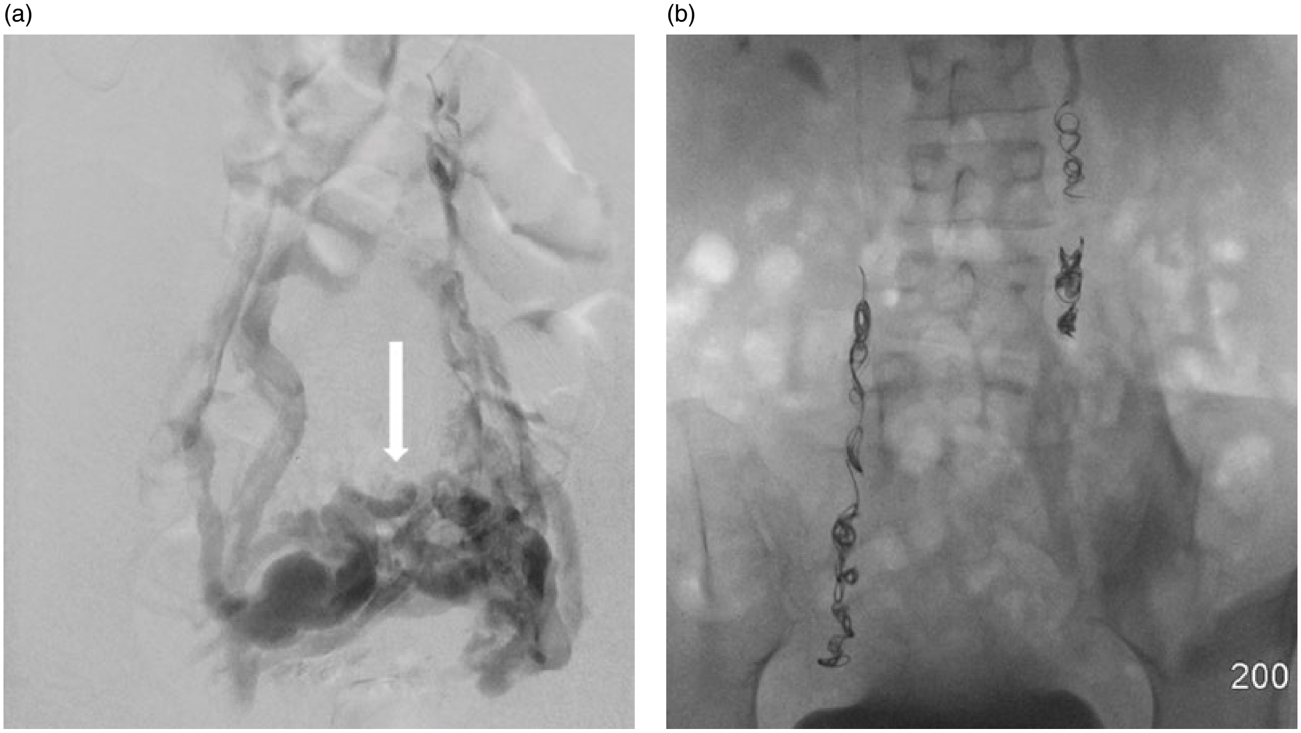

**Figure 127.9** Bilateral gonadal vein embolization for pelvic congestion syndrome. (a) Digital subtraction angiography (DSA) demonstrates enlarged and tortuous pelvic veins with cross pelvic collaterals that were subsequently (b) treated with bilateral gonadal vein embolization.

anastomoses that may result in nontarget embolization, for example reflux of STS into the common femoral veins. Furthermore, many patients demonstrate internal iliac venous insufficiency as the etiology of PCS and can be treated with proximal coil embolization or with sclerosant; however, flow in these vessels may result in migration resulting in nontarget embolization [15]. However, treatment protocols are debated among authors with respect to unilateral versus bilateral treatment, iliac vein treatment, collateral vein embolization despite lack of reflux, and embolization materials [16].

#### Outcomes/complications

With advancements made in technique, up to 100% of patients undergo successful embolization [14]. Postprocedure protocols and follow-up are identical to male varicocele treatment. Nearly 9 out of 10 patients who present with pain have resolution of symptoms within weeks [18, 19]. VAS scores have been reported to decrease from an average of slightly greater than 7 to slightly less than 1. Dyspareunia may be associated with a poor prognosis [17]. Results seem to be favorable when compared to total hysterectomy and oophorectomy. Recurrence rates are hard to quantify as changes in the VAS scores are typically used in patients without physical attributes of PCS; however, recurrence rates as high as 42% have been reported [17], although recent literature suggests that these were gross overestimates [18, 19]. A second embolization treatment may improve clinical outcomes in these patients [20]. Major complications including but not limited to coil migration, vessel perforation, and DVT are rare. An attempt can be made to retrieve migrated coils using a snare device. Patients may experience paraspinal and pelvic pain if sclerosants are used. This is usually self-limiting and controlled with anti-inflammatory pain medications [15]. No effects on menstruation or fertility have been reported [13]. Minimal long-term data are available for patients with endovascular treatments for PCS. Recurrence has been reported in up to 8% of patients up to 4 years after the initial treatment [13].

### Future directions

The cost of treating patients with chronic pelvic pain results in a considerable expenditure of healthcare funds each year [3]. Some consider minimally invasive endovascular therapies as standard of care for the treatment of PCS [20]. Multicenter randomized controlled trials are needed to compare patient outcomes with different treatment options patient with regard to technical success, recurrence rates, complications, and cost-effectiveness [14].

## Introduction

Renal angiography provides a significant diagnostic benefit in patients with a multitude of renal pathology, including trauma, neoplasm, and vascular malformations. In the acute setting, patients with life-threatening renal hemorrhage can benefit from nephron-sparing or total preoperative devascularization. Selective renal arterial embolization is also used for elective treatment of noncancerous renal tumors.

## Renal arterial anatomy

A familiarity with renal vascularity is paramount in order to efficiently perform renal arterial interventions. Bilateral renal arteries arise from the aorta at the level of 1st and 2nd lumbar vertebrae. Most kidneys are supplied by a single vessel (70%). The right renal artery is longer than the left, given the increased distance from the aorta. The kidneys have segmental anatomy as defined by their vascular supply; most commonly there are five segments: apical, upper, middle, lower, and posterior. Usually, the first branch of the renal artery is the posterior division which supplies the posterior segment of the kidney. The anterior division then trifurcates to supply the upper, middle, and lower segments. The apical segment vascular supply is commonly shared with the upper segment; however, there is a 10% incidence of shared vascularity with the posterior segment (Figure 128.1a). Smaller arteries arise from the main renal artery and its divisions to supply the renal pelvis and proximal ureter [1, 2].

Variant renal anatomy is present in nearly one-third of all patients. Most commonly, 30% of variants, there is an accessory, aberrant, or supernumerary renal artery. A vast majority of these vessels originate from the aorta. However, they rarely can stem from any artery within the abdomen and pelvis, such as the lumbar, colonic, pancreatic, gonadal, hepatic, adrenal, and inferior phrenic arteries. Most commonly there is an accessory vessel superiorly to supply the apical segment or inferiorly to supply the lower segment of the kidney. There is a slightly increased incidence of an accessory renal artery on the left than the right. A right-sided renal artery may course anterior to the inferior vena cava. In addition, there may be duplication of renal arteries in up to 10% or patients (Figure 128.1b) [2–4].

## Adrenal vasculature

The adrenal glands have varying vascular supply, and may be perfused by up to three arteries (Figure 128.2). The superior adrenal artery usually arises from the inferior phrenic artery, which may branch off the celiac plexus. The middle adrenal artery commonly stems directly from the aorta. The inferior adrenal artery usually originates from the main renal artery [5]. The adrenal gland may be supplied in part by combinations of this vascular supply; most commonly supply is from two vessels (61%) or three vessels (34%).

An understanding of adrenal vasculature is crucial to an understanding of renal vasculature and pathology. Given the likelihood of a shared vascular supply and regional proximity, disease of one organ may involve the other. Renal trauma or renal intervention may injure the adjacent adrenal gland or its vascular supply (Figure 128.3).

## Horseshoe kidney

Formation of a horseshoe kidney is secondary to aberrant *in utero* renal development. Normally, during the first trimester of gestation, nearly adjacent bilateral metanephric buds of the pelvis are developing into the kidneys. As the gestation progresses the metanephric buds demonstrate external rotation and ascension into the retroperitoneum. As the metanephric buds ascend, their vascular supply arises from progressively more superior renal arteries from the aorta. The most common development aberration is malrotation of one kidney. If the lower poles of the metanephric buds fuse, their ascension halts at level of the inferior mesenteric artery, as the isthmus of this horseshoe kidney is bound superiorly by this vessel (Figure 128.4). Subsequent renal vascularity may vary as numerous adjacent vessels in the lower abdomen and pelvis may supply the organ [6].

Renal arterial interventions of a horseshoe kidney require thorough mapping of the vascular supply, as there may be multiple vessels which can stem from the aorta or the iliac arteries.

## Technical issues

### Vascular access

Every angiographic procedure requires a proper and skillfully established vascular access. Arterial access is commonly performed via the modified Seldinger technique, and can be aided with sonographic imaging in addition to physical exam. The common femoral artery is traditionally and most commonly used. However, radial, brachial, or axillary arteries may be utilized [7, 8].

Commonly, arterial access is achieved with a 21 gauge micropuncture needle under sonographic guidance. Serial dilatation of the puncture site is performed and followed by placement of a vascular access sheath over a wire. Sheath sizes commonly range between 4 and 6 Fr. Vascular interventions on small children or neonates may be performed with a 4 Fr system without the use of a vascular sheath. In rare instances, the umbilical artery can be catheterized in newborns.

### Renal artery catheterization

The renal artery may be targeted directly to reduce patient radiation and intravenous contrast dose, especially in cases where prior imaging is available to depict the patient's anatomy. Alternatively, an abdominal aortogram may be performed. Multiple catheters are available for arterial selection. Commonly, the catheter selection is based on the operator's preference. In certain instances, the short left or stenotic renal artery may be selected with a reverse curve catheter, as this catheter will provide a more stable access. Microcatheters are used in a coaxial technique to target smaller distal renal arterial branches. Selective targeting of renal vessels aids in increased clarity of regional pathology, and allows for nephron-sparing embolization.

### Embolization materials

Several embolic agents exist and demonstrate unique characteristics allowing for effective use in various clinical scenarios. The agents may be permanent or temporary.

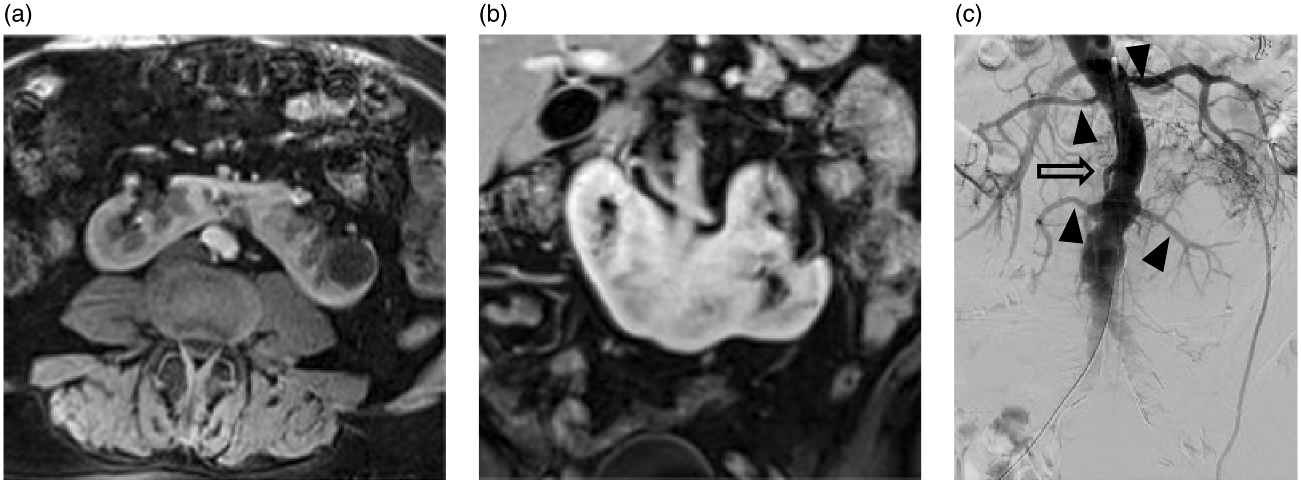

**Figure 128.4** Horseshoe kidney. (a) Axial and (b) coronal postcontrast MR images of a horseshoe kidney demonstrate renal fusion of the lower renal poles. (c) Aortogram demonstrates numerous renal arteries (arrowheads). Note the abnormally high location of the inferior mesenteric artery (black open arrow).

Temporary arterial embolization materials, such as microfibrillar collagen, gelatin foam, or biodegradable particles may be used in instances where delayed vessel reperfusion is appropriate. The occlusive effect varies and may last from 3 to 90 days depending on the agent used [7]. Permanent embolization agents include vascular plugs, coils, particles, sclerosing agents, and glue.

Coils are used quite commonly and may be detachable or nondetachable. The detachable coils remain attached to the wire until they are appropriately formed within the targeted vessel. Permanent embolization particles are produced in sizes ranging from 40 to 2000 μm. Small particles range from 40 to 300 μm and are commonly used to embolize distal tumor vessels to attain tumor necrosis. In certain tumors, such as angiomyolipomas, larger particles may be used to achieve tumor necrosis. In general, the larger particles provide a rapid vascular occlusion where tissue necrosis is not the primary goal. These large particles are commonly used as a means of preoperative embolization and to stop anastomosed arteriovenous shunting.

Several liquid embolic agents are available, including ethanol, glue, and several newer nonadhesive agents. The ethanol used ranges from 94% to 99% concentration, and causes endothelial damage which induces rapid vessel occlusion. Ethanol is commonly mixed with radiopaque iodized oil. The oil makes the injection visible on fluoroscopy. The oil also provides the added benefit of lengthening the vascular endothelial exposure to the ethanol. Ethanol injection is painful and appropriate pain management is advised.

*N*-Butyl-2-cyanoacrylate glue is a liquid embolic agent that polymerizes upon contact with blood or ionic substances. As with ethanol, the glue is mixed with radiopaque iodized oil. The glue consistency may be diluted to match target vessel flow and decrease the odds of nontarget embolization. This balance is rather precise and requires significant expertise and experience. Also available is an additional nonadhesive liquid agent composed of an ethylene vinyl alcohol copolymer combined with a radiopaque tantalum powder. This mixture hardens, forming a shapeable dense cast for several minutes, and is particularly useful when slow embolic delivery is required [7].

Postembolization arteriograms are always performed. It is important to perform a proximal renal artery injection following the angiogram of the occluded vessels. This allows for evaluation of the presence of additional arteries supplying the targeted area. Occasionally after target embolization is performed, additional feeding vessels to the area of interest are identified on aortogram, as vascular redistribution may occur.

Completion of the angiographic procedure involves removal of the access sheath or catheter. Hemostasis of the puncture site has classically been performed with manual compression of the vascular access site. However, multiple hemostatic patches are available which can be used with or in lieu of compression. If the radial artery was used for vascular access, then wearable compression-assisting devices are available to achieve hemostasis. In addition, vascular closure devices are also widely used. These devices provide added comfort to the patient and operating physicians when compared to manual compression.

## Postembolization management

Postembolization management involves prevention of arterial access site hemorrhage and management of the postembolization symptoms. For femoral access cases, strict bed rest with extension of the punctured extremity is employed. Common postembolization symptoms are rather nonspecific and include: nausea, emesis, fever, leukocytosis, as well as flank, back, and/or abdominal pain. These symptoms usually develop within 72 hours post procedure [9]. These symptoms are medically managed with use of antiemetic, anti-inflammatory, and pain medications with intravenous hydration. These symptoms are the result of the systemic inflammatory response, and a septic workup is not required.

## Treatment of traumatic and iatrogenic hemorrhage

Blunt force or penetrating injury are the most common etiologies of renal trauma [10, 11]. Blunt trauma is far more common and penetrating renal injuries are usually iatrogenic, following surgery, biopsies, or percutaneous urological procedures (Figure 128.5a–c).

Blunt renal injury is typically graded with computed tomography (CT) findings, and as per the American Association for the Surgery of Trauma which guides the need for surgical intervention. Low-grade I–II renal injuries are managed conservatively with hospitalization and blood transfusions as needed. High-grade III–V injuries are usually treated with either surgery and/or intervention. Renal angiogram and embolization may be performed alone or in conjunction with surgery. Preoperative embolization may minimize bleeding and facilitate nephron-sparing intervention.

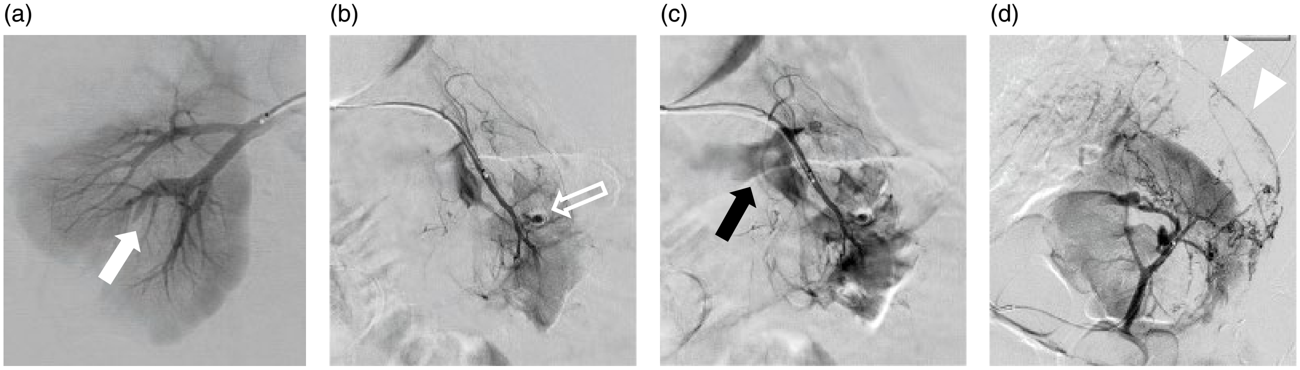

**Figure 128.5** Direct signs of vessel injury. (a) Arterial cutoff sign (white arrow). (b) Pseudoaneurysm (white open arrow). (c) Arteriovenous fistula (black arrow), early filling of the left renal vein. (d) Active contrast extravasation (white arrowheads).

Identification of hemorrhagic sources on angiography require a fundamental knowledge of the signs of bleeding. There are two types of angiographic signs of bleeding: direct and indirect. The indirect signs of bleeding are vascular spasm, hematoma, and displacement of the arteries from their usual course – usually by an underlying hematoma. The direct signs of bleeding include: abrupt termination of the artery (vessel cutoff sign), formation of a pseudoaneurysm, presence of an arteriovenous fistula and/or extraluminal contrast extravasation. Vessel cutoff sign or abrupt vessel termination represents arterial thrombosis as a result of complete or partial vascular transection. Pseudoaneurysms are areas of lobular contrast accumulation adjacent to the ruptured vessel confined by regional soft tissues. The pseudoaneurysms present with intermittent bleeding when the surrounding tissues periodically separate secondary to increasing pressures. Arteriovenous fistulas are an abnormal direct communication between the imaged artery and vein, and are identified angiographically with the presence of an early draining vein. Contrast extravasation reflects active hemorrhage (Figure 128.5) [11].

In patients with renal hemorrhage, renal angiography not only elucidates anatomic source(s) of hemorrhage but also allows for a minimally invasive treatment with a high rate of efficacy. Arteriography should be considered first line for recalcitrant and refractory bleeding in iatrogenic cases.

## Angiography and embolization of renal tumors

Identifying neoplasms angiographically requires knowledge of "tumor vascularity." These findings are similar for neoplasms in any part of the body. They include abnormal vascular tortuosity, luminal irregularities, aneurysms, pseudoaneurysms, hypervascularity, parasitized vessels, arteriovenous shunting, and early contrast opacification and delayed washout – also called the "mother-in-law sign" (Figure 128.6). Tumor vessels are more porous and lack the ability to control bleeding as normal arteries do, and as a result are susceptible to hemorrhage, especially as the tumors increase in size [12]. Not uncommonly, it is impossible to determine the nature of a tumor based on angiographic appearance, and using corresponding cross-sectional imaging is of the utmost importance.

### Renal angiomyolipomas

Renal angiomyolipomas (AMLs) are benign tumors containing fat, vascular, and smooth muscle components (Figure 128.7). They are sporadic in approximately 80% of patients. In approximately 20% of patients, AMLs are most commonly associated with a phakomatosis [13]. The sporadic tumors are more frequent in women and tend to be asymptomatic in approximately 75% of cases. Nearly 15% of patients with AMLs present with lesion hemorrhage. Multiple AMLs are seen in 15% of affected patients. The most common hereditary conditions associated with AMLs are tuberous sclerosis, von Hippel–Lindau syndrome, and neurofibromatosis type 1.

Clinical presentations of AML include palpable masses, flank pain, urinary tract infections, hematuria, renal failure, or even hypertension. Renal AMLs are prone to hemorrhage, and the risk of hemorrhage increases with the tumor size. At 4 cm or greater, the lesion has a significant bleeding risk (>50%) and preemptive embolization should be performed [12]. Surgical resection is an option, but this is generally reserved for rare cases where embolization cannot be performed.

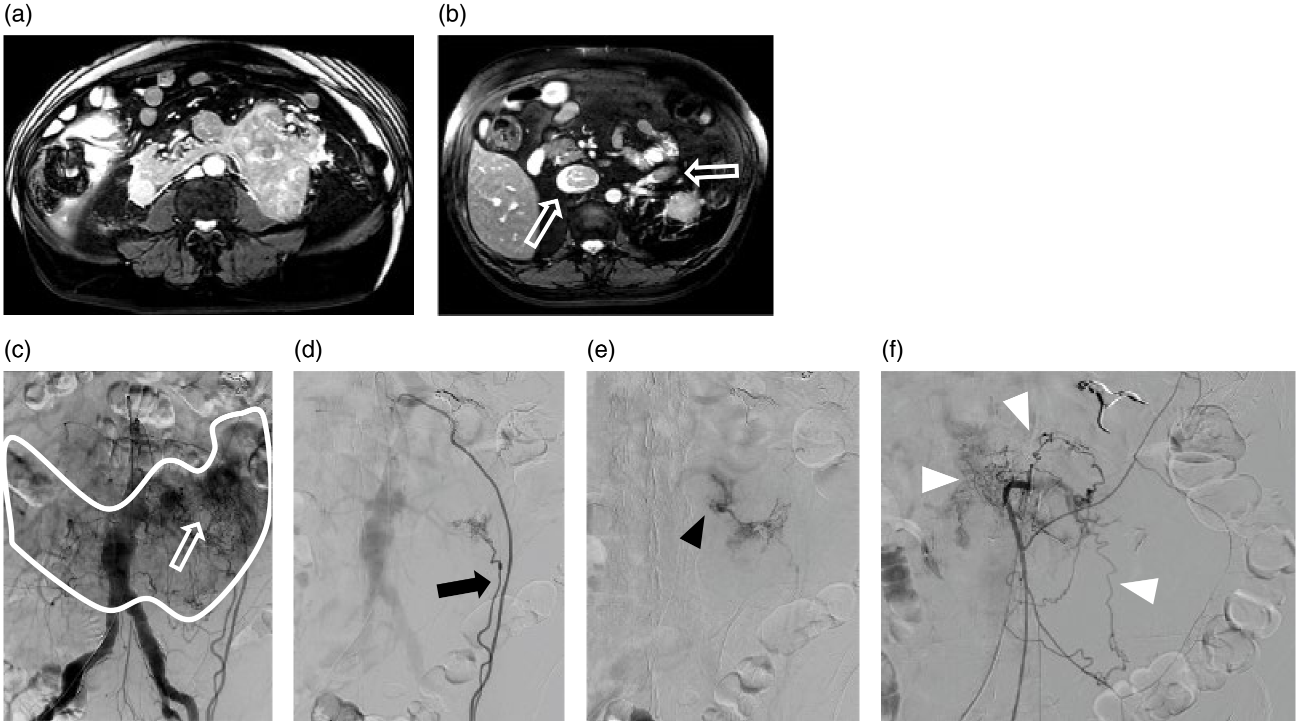

**Figure 128.6** Renal cell carcinoma, horseshoe kidney. (a) Axial T2-weighted MR images demonstrate a renal mass involving the left anterior aspect of the horseshoe kidney. (b) Tumor thrombus in the left renal vein and inferior vena cava (white open arrows). (c) Aortogram demonstrates hypervascular renal cell carcinoma (white open arrow) within the left portion of the horseshoe kidney (delineated). (d) Selective left gonadal arteriogram. Parasitic artery (black arrow) supplies the left renal mass. (e) Early left renal vein drainage (black arrowhead). (f) Selective inferior mesenteric arteriogram (IMA). Numerous parasitic vessels from the IMA (white arrowheads) supply the renal mass.

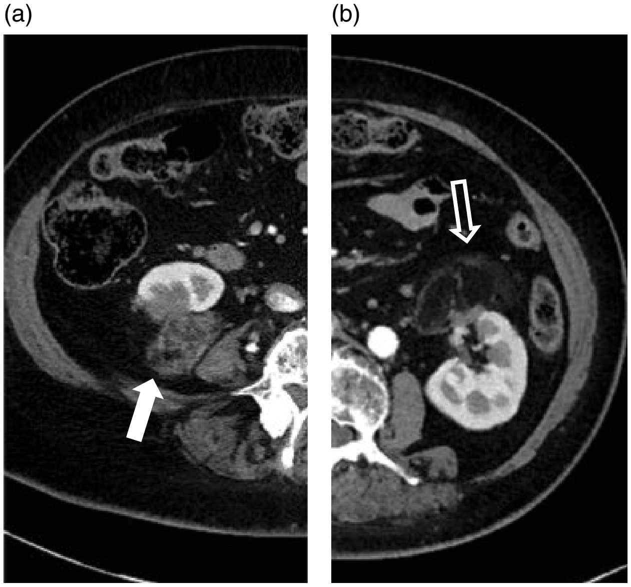

**Figure 128.7** Bilateral angiomyolipomas. Contrast-enhanced CT images of a patient with tuberous sclerosis. (a) Enhancing fat-containing lesion through the lower pole of the right kidney (white arrow). (b) Similar fat-containing lesion at the upper pole of the left kidney (white open arrow).

AMLs usually have well-demarcated margins, irregularly dilated vessels, aneurysms, and lack of arteriovenous shunting. Sporadic AMLs, compared to other renal tumors, typically demonstrate a single feeding artery. Particle embolization of an AML will decrease tumor vascularity, and will gradually lead to decreased tumor size and risk of hemorrhage (Figure 128.8). Embolized AMLs require follow-up, and approximately one-third of cases will require re-embolization. AMLs with acute hemorrhage can also be successfully treated with emergent embolization. AML arterial embolization is a well-tolerated, safe, durable, and effective kidney-sparing therapy [12, 14].

## Preoperative embolization for large tumors

Preoperative renal embolization can be helpful before radical nephrectomy for treatment of large renal neoplasms, such as renal cell carcinoma (RCC). It can minimize the intraoperative hemorrhage and decrease

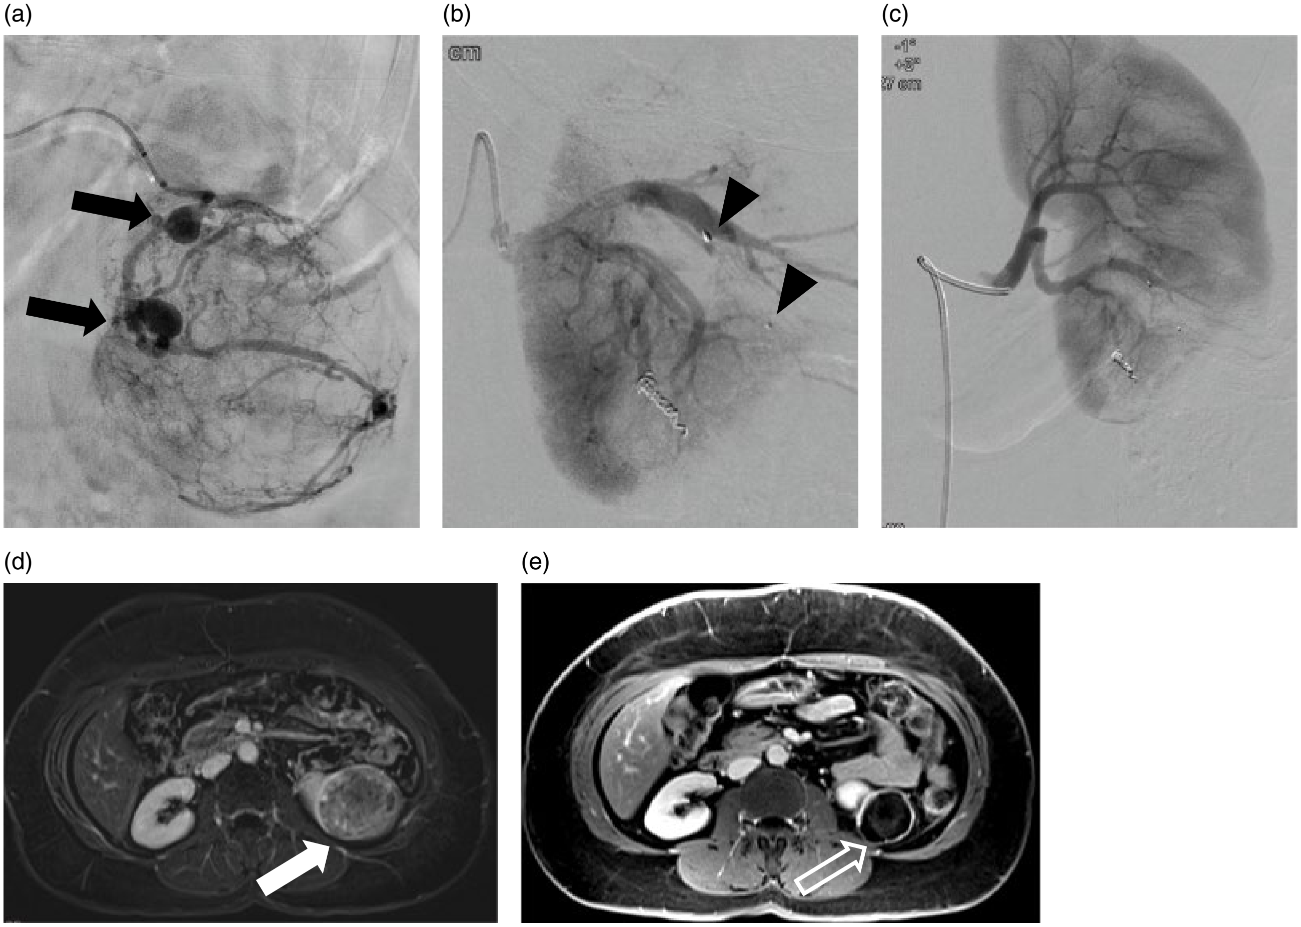

**Figure 128.8** Sporadic angiomyolipoma (AML) with interval treatment. (a) Subselective left renal arteriogram demonstrates irregularly dilated and tortuous vessels with saccular aneurysms (black arrows). (b) A microvascular plug (black arrowheads) and coils were used to devascularize the lesion. (c) Postembolization arteriogram demonstrates preserved vascular supply to the remainder of the kidney. (d) Preprocedural contrast-enhanced MRI demonstrates the large enhancing AML (white arrow). (e) Follow-up MRI demonstrates decreased size of the AML with absent internal vascularity (open white arrow).

the overall time of the surgery [15], which translates to a decrease in perioperative morbidity and mortality [7]. Arterial embolization of RCC is typically performed within 24 hours of the planned nephrectomy (as in previously mentioned Figure 128.6).

## Pediatric renal tumors

Selective renal arterial embolization can be helpful in the management of pediatric primary renal neoplasms such as Wilms' tumors, AMLs, rhabdoid, metanephric adenomas, etc. [16, 17]. For example, it has been used to stabilize patients who presented with active bleeding secondary to ruptured Wilms' tumors in order to bridge them to a complete nephrectomy (Figure 128.9) [18].

## Conclusion

Renal angiogram and embolization plays an important role in the management of urological patients. It can enhance the urological practice and improve clinical outcomes. These procedures can be used electively or emergently, preoperatively, or independently in patients with a range of urological diseases. Continuous advancement in digital technology, imaging, and material science increases efficacy and safety of these procedures and will continue to be an important asset in management of urological patients.

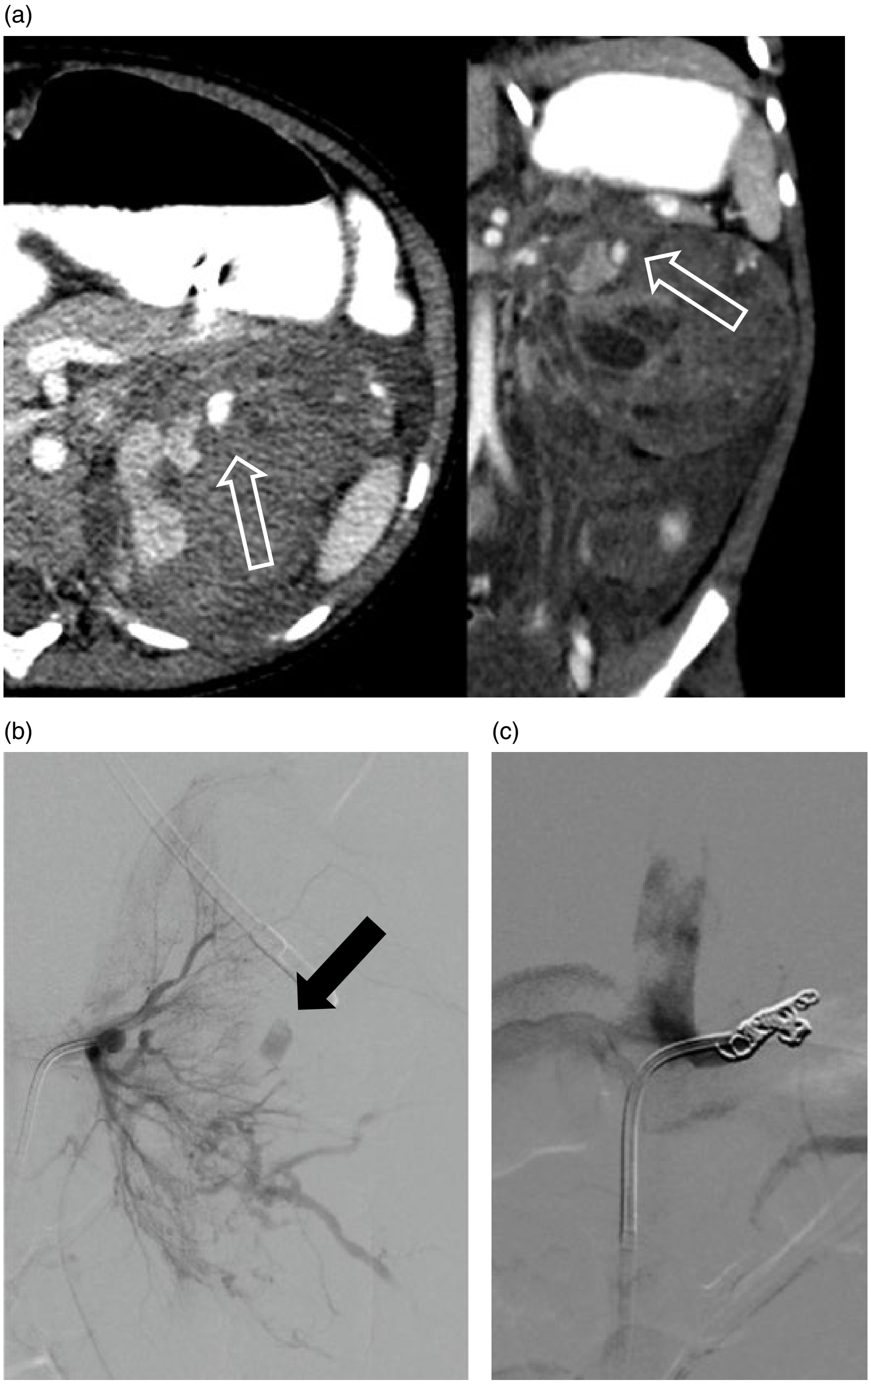

**Figure 128.9** Hemorrhagic Wilms' tumor. ## Introduction

Symptoms of benign prostatic hyperplasia (BPH) affect a large number of middle-aged men, estimated to be more than 15 million in the United States, with an estimated cost to the healthcare system of US$3 billion annually [1]. Improving treatment of BPH therefore represents a major concern for the American healthcare system as an area for potential cost savings and quality-of-life improvements.

Symptoms related to BPH are commonly referred to as lower urinary tract symptoms (LUTS), and are broadly categorized into two categories: storage and emptying. The generally accepted standards for the evaluation of BPH symptoms includes the International Prostate Symptom Score (IPSS), which is used to assess changes in quality of life related to LUTS [2] and consists of a questionnaire covering symptoms of frequency, urgency, and nocturia among others. The first-line approach to treatment of LUTS commonly includes lifestyle changes such as management of fluid intake and output. Medical therapy with oral agents is the next step in symptom management and can include alpha-blockers (tamsulosin, terazosin, etc.), 5-alpha-reductase inhibitors (finasteride, dutasteride), anticholinergic agents, or a combination of these agents [2]. When patients can no longer be managed on one or more of the above medications, definitive management is generally offered with either minimally invasive or surgical therapy.

This chapter explores the technique and role of selective prostate artery embolization (SAPE) as a treatment for LUTS secondary to BPH as it compares to conventional definitive treatment options.

## Procedures for management of benign prostatic hyperplasia

Transurethral minimally invasive treatment options include transurethral needle ablation (TUNA) and transurethral microwave thermotherapy (TUMT). Both techniques involve using heat energy from either radiofrequency probes (TUNA) or a microwave probe (TUMT) to induce thermal necrosis of the adjacent prostate tissue. Criticisms of TUNA have centered around the lack of prospective randomized data on the technique and the apparently high lifetime retreatment rate (46% at 3 years in one study of 102 patients) [3]. Efficacy of TUMT has improved as technology has improved the ability of transurethral microwave probes to generate sufficient temperatures for prostate tissue ablation. It is estimated that around 80 000 TUMT cases are performed each year in the United States [2]. Similar to TUNA, concerns surrounding TUMT have focused on the lack of quality prospective data on the technique, especially given the technical differences in the devices available for the procedure over the years. Ultimately, the major benefits of TUNA and TUMT seem to be offering patients a lower rate of erectile dysfunction than conventional surgical management, with the major concern surrounding the treatments being the possible need for retreatment.

More recently, laser-based transurethral options have become a popular option for BPH treatment. Treatments include holmium laser ablation of the prostate (HoLAP), enucleation of the prostate (HoLEP), and resection of the prostate (HoLRP), along with photoselective vaporization of the prostate (PVP). All therapies use a transurethral laser probe to heat the periurethral prostatic tissue, with

Companion website: www.wiley.com/go/smith/textbookofendourology

or without an additional mechanical component of resection. Use of laser therapies for BPH has been associated with decreased catheterization time and lower complications rates. Data on the techniques are limited by short follow-up and rapid evolution of device technology.

Surgical therapy for bladder outlet obstruction (BOO) related to BPH is defined as the mechanical debulking of tissue within the prostatic fossa. Techniques for debulking prostate tissues have evolved over the years, with options ranging from open prostatectomy to transurethral laser ablation and traditional TURP. Open (simple) prostatectomy represents the most invasive treatment option for BPH, and is generally reserved for patients with prostate volumes greater than 80–100 ml, bladder calculi, or bladder diverticula. It is associated with longer hospital stays and higher transfusion rates than TURP [4].

TURP remains the gold standard treatment option for LUTS related to BPH, and involves the use of a transurethral resectoscope to debulk the periurethral prostatic tissue. Short-term complications of the procedure include hematuria, while long-term complications can include urethral stricture, sexual dysfunction, and dilutional hyponatremia. The incidence of dilutional hyponatremia has decreased with the implementation of bipolar transurethral resection using normal saline as an irrigant compared to glycine. There has been only one reported randomized controlled trial comparing TURP and SAPE [5]. In the study, technical success rates for TURP and SAPE were comparable (100% and 94.7%, respectively). Patients were followed for 2 years. A compelling finding was the apparent trend toward greater improvement in IPSS, quality of life, peak urinary flow rate ($Q_{\max}$), and postvoid residual bladder volume (PVR) after one and three months in the TURP group, with the SAPE group ultimately reaching similar values at six months with sustained results for the remainder of the study period. The authors discussed the logical nature of this outcome, given that SAPE is not an instantaneous ablative technique. One advantage of SAPE appeared to be the relative safety of the procedure; two TURP patients required transfusion and another required intensive care unit admission, versus 0 in the SAPE group. Patients undergoing prostate artery embolization have reported improvement in erectile function, possibly secondary to an increase in blood flow to the pudendal artery following embolization.

## History of selective arterial prostate embolization

Embolization of prostate arteries has long been used to control serious bleeding after biopsy or prostatectomy. DeMeritt and colleagues described in their 2000 paper the first report of a patient experiencing decreased prostate volume following SAPE of the right inferior vesicle artery, which was used at the time for severe hematuria following prostate biopsy [6]. They discovered that prostate volume was reduced by 52% at 5 months and 62% at 12 months, suggesting that SAPE may be a clinically viable option for the treatment of BPH. SAPE has also been referred to as prostate artery embolization (PAE); this nomenclature is also used in uterine artery embolization (UAE). However, by using SAPE as an acronym we attempt to set it apart from UAE, which is technically less challenging.

Animal studies using triacrylic gelatin microspheres (Embosphere; Merit Medical, South Jordan, UT, USA) in dogs and pigs demonstrated the efficacy of embolization with spherical microparticles, resulting in decreased prostate volume with no apparent decrease in sexual function [7, 8]. Initial human implementation of SAPE for the treatment of BPH was described in 2010 by Carnevale et al. in two patients, both of whom experienced a steady decrease in prostate volumes up to six months [9]. A subsequent study by Pisco et al. demonstrated a mean improvement in IPSS of 6.5 points ($P = 0.005$) in a cohort of 15 patients treated with SAPE [10].

A single-center prospective study of 72 patients evaluated for possible SAPE, of whom 20 underwent treatment, revealed 19 of 20 patients with improvement in symptoms at 1, 3, and 6 months. Similar improvements in quality of life and sexual function were noted [11]. There were no major or minor complications in the study. Findings suggested that SAPE is a safe and effective option for treatment of BPH. A more recent meta-analysis examined the results of six studies of SAPE comprising a total of 481 patients revealed overall improvement in $Q_{\max}$, PVR, IPSS, and quality of life endpoints at 12 months, with a low incidence of serious adverse events (0.3%) [12]. They report a relatively high rate of minor adverse events (32.93%), with the most common being transient acute urinary retention and dysuria.

## Benign prostate hypertrophy workup and preoperative assessment

According to the 2010 AUA Guidelines for the Management of BPH, workup should follow an algorithmic approach as adapted from the 2009 article by Abrams et al. [13]. Assessment of LUTS may include a quality-of-life assessment using the IPSS, as well as quantitative measures such as PVR, prostate volume (either by ultrasound or MRI), urodynamic studies (generally $Q_{\max}$ and peak detrusor pressure ($P_{\text{det}}$) at $Q_{\max}$), and a urinalysis.

At our institution, we consider patients for prostate artery embolization with:

- LUTS for >six months
- IPSS score >13
- $Q_{\max} < 12$ ml/s and or urinary retention
- Prostate volume larger than 40 ml as assessed by MRI
- Negative screening prostate MRI (no lesions suspicious for cancer)
- Symptoms refractory to medical therapy or contraindications to medical therapy
- Baseline prostate specific antigen (PSA) <3.5 ng/ml.

In patients with baseline PSA >3.5 ng/ml, the patient must be counseled on risks and benefits of prostate cancer screening with their urologist. Furthermore, the subject must meet one of the following criteria:

- Negative prostate cancer screening (minimum 12 core prostate biopsy) within 2 years of the procedure
- No MRI visible prostate lesions suspicious for cancer: (negative prostate MRI)
- Negative targeted biopsy of any suspicious lesions on MRI along with a standard biopsy within the last 2 years.

Contraindications include:

- active urinary/prostate infection
- prostate cancer (clinically significant)
- neurogenic bladder
- urethral stricture or other urethral conditions contribution to BOO.

A conversation with the patient about future interest in fertility is warranted prior to therapy.

## Preprocedure imaging

Ultrasound and MRI are both able to provide estimates of prostate volume prior to embolization, providing a helpful baseline for later assessment of the treatment effect. Prostate ultrasound is operator dependent and relies on the ellipsoid volume formula to calculate prostate volume. MRI can provide a slice-by-slice volumetric assessment of prostate volume, making it superior to ultrasound in accuracy and the study of choice in our institution. In addition, MRI is able to identify unknown prostate cancers, thereby altering the course of treatment for a given patient. Efforts have been made to standardize reporting of prostate MRI findings, with the latest iteration from the American College of Radiology being PI-RADS v2 [14]. Patients with a suspicious MRI-visible lesion require discussion and most likely a biopsy before meeting criteria for prostate embolization. A prostate with characteristic findings of BPH is shown in Figure 129.1.

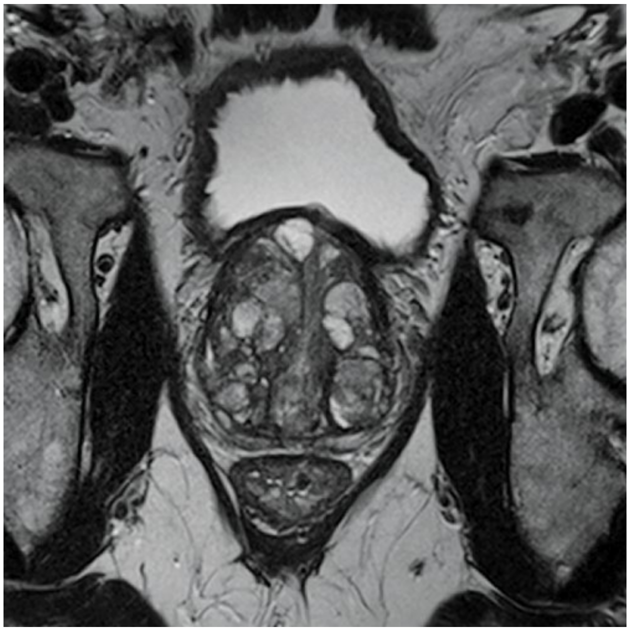

**Figure 129.1** High-resolution small field-of-view T2-weighted MRI of the prostate. Round high-signal foci within the central gland represent mixed-type BPH nodules with characteristic cystic and glandular components. Predominantly low-signal areas correspond to pure stromal-type BPH nodules. Expansion of the gland results in mass effect on the adjacent urinary bladder anteriorly.

## Technique

SAPE can be safely completed using moderate conscious sedation with midazolam and fentanyl. Preprocedure, we recommend placement of a Foley catheter balloon in the bladder, filled with 10–20% iodinated contrast, as a means to aid localization of the gland in its relationship to the bladder neck.

### Transradial approach

We typically perform SAPE via left transradial approach as previously described [15], though a transfemoral approach is also well-established. Assessment of palmar arch patency/presence of adequate collateral circulation is performed prior to access via the Barbeau test (modified Allen test) using pulse oximetry as previously described [16]. A type D waveform (i.e. lack of any ulnar artery collateral flow to the arch) is an absolute contraindication to radial access.

Initial radial access is obtained using ultrasound guidance and a micropuncture kit consisting of a 21-gauge needle and 0.021-inch nitinol wire. A 5 Fr hydrophilic sheath (Glidesheath™, Terumo Medical, Somerset, NJ, USA) is then advanced over the wire and secured using an adhesive bandage (Tegaderm™, 3M Medical, St. Paul, MN, USA). A solution of 2 mg verapamil, 3000 units of heparin, and 200 µg of nitroglycerin are then diluted in the patient's blood and administered through the sheath to prevent arterial spasm and thrombus formation.

Catheters used for transradial uterine artery embolization can generally also be used for SAPE given their similar technical considerations. We use a 130 cm 5F Select BER Catheter (Penumbra, Alameda CA, USA) and a 180 cm 0.035-inch Benston wire to advance the catheter up the left arm, over the aortic arch and down the descending aorta into the anterior devision of the left internal iliac artery. A 150 cm microcatheter (2.0Fr, PROGREAT, TERUMO, USA) is then used with an 0.016-inch hydrophilic wire (Fathom, Boston Scientific, MA, USA) to select prostatic artery branches. We sometimes find it helpful to use a smaller profile microcatheter, 1.7–1.9 Fr with a 45° angled tip microcatheter (Codman Neuro, DePuy Synthes, Wokingham, UK) in combination with a Silverspeed 0.014-inch hydrophillic wire (Medtronic, MN, USA), to navigate smaller prostatic vessels. Please take into consideration a patient's height when selecting catheters and patients for radial artery access.

## Transfemoral approach

If a transfemoral approach is preferred, catheters can again be selected from those used for uterine artery embolization. A 5 Fr cobra or vertebral artery diagnostic catheter can be used to select the anterior division of the internal iliac artery. A microcatheter and 0.018-inch hydrophilic wire are similarly recommended for subselection of prostatic artery branches. An alternative also includes the use of a pudendal artery catheter to allow for ipsilateral and contralateral access without the use of a Waltman loop.

## Angiography/selection of embolization site

Initial angiography is generally performed from the anterior division of the internal iliac artery using digital subtraction angiography (DSA). An ipsilateral 25–55° oblique view is used to assess the blood supply to the prostate, and can be maintained to facilitate catheterization of the internal vesicle artery [17]. Cranial angulation of 10–15° can also help with visualization of the prostatic vasculature. Figure 129.2 shows an example DSA image with anatomic labels.

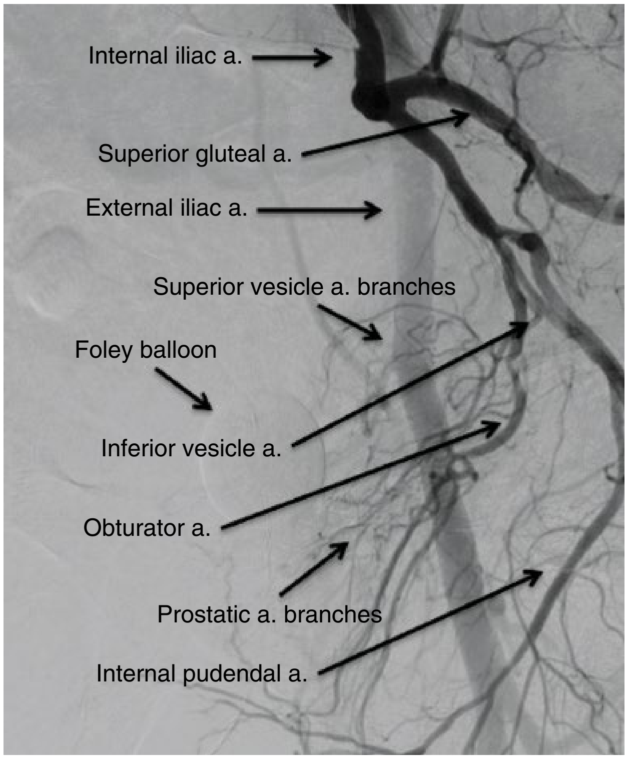

**Figure 129.2** Digital subtraction angiography performed from an ipsilateral 35° approach. Iodinated contrast was injected via a 5 Fr catheter positioned in the proximal internal iliac artery.

Numerous papers have described the benefit of cone-beam CT (CBCT) as a means for preventing nontarget embolization during SAPE [18, 19]. This can be performed prior to embolization from the prostatic artery. We agree, and furthermore if available prefer use of vessel detection software (EmboGuide, Philips Healthcare, Amsterdam, The Netherlands), which provides assistance with automatic feeding artery detection and live image guidance during the procedure. EmboGuide setup requires CBCT with an injection at the level of the anterior division of the internal iliac artery using approximately 3–4 ml/s for 10 seconds (total volume 30–40 ml) of contrast following a 5 second delay (Figure 129.3).

Further subselection of the prostatic arteries should ensure that any collateral vessels supplying the bladder, penis, rectum, or gonads have been passed, with the microcatheter ultimately stationed distally within the prostatic artery. CBCT angiography may be performed to confirm the vascular distribution within the subselected branch to help lower the risk of nontarget embolization. Figure 129.4 shows an example of a prostatic artery CBCT angiogram.

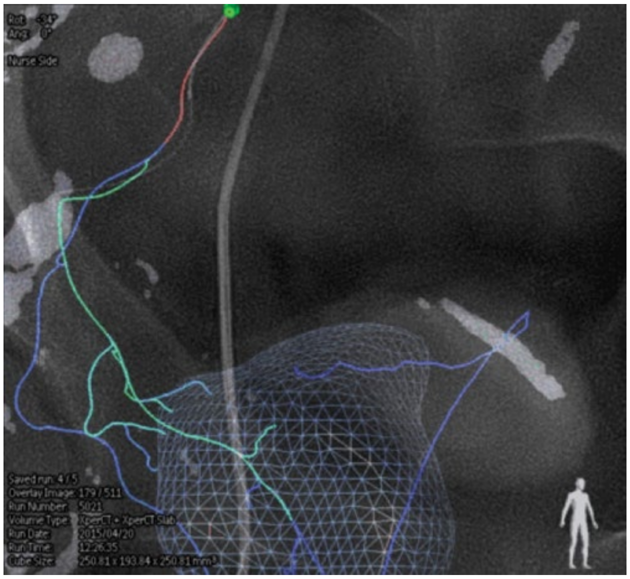

**Figure 129.3** Cone-beam CT angiogram using EmboGuide (Phillips) guidance software. A CBCT angiogram was performed using EmboGuide software with microcatheter positioned in the proximal portion of a right prostatic artery branch. Red, green, and blue lines indicate likely prostatic artery locations. Imaging is projected on the in-room monitors and correspondingly changes position as the operator manipulates the table and imaging angle.

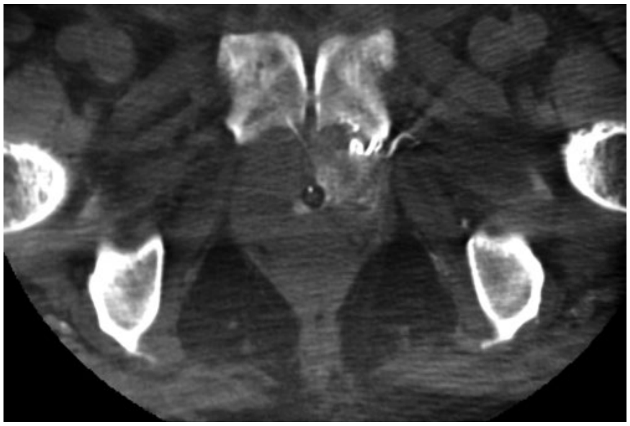

**Figure 129.4** Axial cone-beam CT angiography, mid-gland. Intraprocedural CBCT angiography was performed with contrast injection via microcatheter positioned in a prostatic artery branch. Parenchymal enhancement of the left lobe of the prostate gland is seen, along with opacification of the injected prostatic artery. A Foley catheter is seen in the prostatic urethra.

## Embolization

Arteries supplying the prostate gland generally measure between 200 and 400 μm. Among the generally accepted media for embolization are 300–500 μm Embosphere® Microspheres (Merit Medical, South Jordan, UT, USA), though other operators have described successful use of other spherical agents [11] (Embozene 100–400 μm, Boston Scientific) and non-spherical agents (PVA) [6]. A randomized prospective study comparing the use of smaller (100 μm) and larger (200 μm) PVA particles revealed greater reduction in prostate volume and PSA in the 100 μm group [20]. The rational is that smaller diameter particles achieve a deeper penetration within the prostatic vasculature, possibly down to the periurethral level, though these may cause more irritative voiding symptoms. Embolization particles as small as 40 μm have been evaluated without adverse side-effects [21].

Particles are diluted with equal parts saline and iodinated contrast medium and suspension is achieved via repetitive inversion. Embolization is performed to near-stasis.

## Vascular anatomy

In the setting of BPH, prostatic arteries will generally be hypertrophic, improving visibility during the procedure. Still some operators prefer that their patients undergo CT angiography (CTA) of the pelvis prior to SAPE. The utility of this technique was described by Bilhim et al. [22]. In their study of 21 male patients using DSA in all patients and CTA in seven patients, the most common site of prostate artery origin among patients was the internal pudendal artery (56% of sites), with a common gluteal/pudendal trunk origin representing the next most common site (28%). Two separate feeding vessels were identified in 24% of pelvic sides.

CTA was described by Bilhim et al. as "very useful as a pre-intervention tool allowing planning of the intervention, and was able to detect small vessels such as the prostatic arteries," allowing "definition of the iliac artery trajectory and atherosclerotic changes." We do not routinely perform CTA prior to SAPE, as we feel CBCT provides adequate procedural guidance. A helpful alternative could be MRA obtained as part of a preprocedural prostate MRI, however this method has not yet been validated as a tool for procedural guidance and may not have resolution yet to delineate this anatomy adequately.

A common complicating factor during SAPE is the presence of extensive atherosclerosis, which is expected given the average age of patients with LUTS from BPH. In previous studies, this was the most common reason cited as a cause for unilateral or bilateral technical failure in embolization [11].

On completion of the procedure, the sheath is removed. For transradial procedures, a compression band (TR Band®, Terumo) is used to achieve hemostasis as previously described [23], allowing patients to ambulate

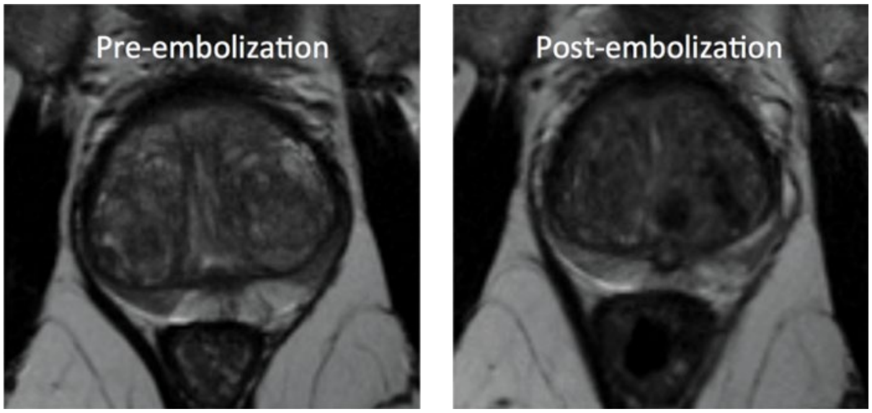

**Figure 129.5** Pre- and postembolization prostate MRI. Axial T2-weighted prostate MRI was obtained before and three months after SAPE. Prostate volume in the postembolization was 47 ml compared to 74 ml pre-embolization. Areas of low signal in the postembolization image represent areas of ischemia/infarct.

immediately after the procedure. Arterial closure devices may be used for transfemoral procedures at the operator's discretion.

## Postprocedure follow-up

Patients at our institution are seen for follow-up visits at 1, 3, 6, and 12 months. At each visit, the patient is asked to fill out the IPSS and quality-of-life surveys. At the 3, 6, and 12-month visits, $Q_{\max}$ and PVR are assessed.

Postprocedural imaging may be performed at the interventionalist's discretion; at our institution, prostate MRIs are performed at 1, 6, and 12 months to monitor for response, if the patients are on study. The primary goal of imaging is assessing change in prostate volume rather than parenchymal architecture, therefore ultrasound may be utilized as a cheaper, less accurate alternative as warranted. Examples of pre- and postembolization prostate MRI are shown in Figure 129.5.

## Conclusions

In summary, SAPE has the potential to play a larger role in the treatment of LUTS secondary to BPH, with published randomized trial data demonstrating comparable outcomes to TURP at 6, 12, and 24 months with the added benefit of improved erections and maintenance of normal ejaculatory function.

## Introduction

The current standard for prostate cancer (PCa) diagnosis is transrectal ultrasound (TRUS)-guided biopsy to obtain 12 cores of tissue from the prostate in a systematic fashion. Systematic biopsy refers to standardized geographic sampling of regions, but this method is “blind” to specific areas that may harbor disease. Since the advent of prostate specific antigen (PSA), TRUS biopsy data have shown that a proportion of PCa diagnosed is low risk, clinically indolent, and portends an excellent prognosis [1]. Given the current lack of comprehensive understanding of PCa biology, such early detection may lead to the overtreatment of cancers unlikely to affect a man in his lifetime. This is compounded by the underdetection of high-risk cancers that may be missed given the current limitations of TRUS-guided biopsy. There remains a need for interventions to better distinguish between clinically actionable disease that contributes to prostate cancer-specific patient mortality and those that can be actively monitored safely. Unfortunately, there is no single modality that provides cost-effective, rapid, high-resolution imaging to define potential PCa targets. Targeted prostate biopsy, derived from regions of interest identified on magnetic resonance imaging (MRI) may provide such an opportunity. TRUS offers real-time imaging while sacrificing spatial image quality, whereas MRI offers high-resolution imaging to better delineate discrete lesions. Fusion of multiparametric MRI (mpMRI), which combines anatomic and functional sequences, with real-time TRUS now facilitates a more precise prostate biopsy resulting in improved PCa diagnosis, risk stratification, and staging.

This chapter reviews the general paradigm of mpMRI-TRUS fusion biopsy (FBx), its indications, and provides an overview of the workflow for this novel technology. Finally, we will review the commercially available mpMRI-TRUS FBx platforms on offer.

## Multiparametric prostate MRI

The initial and most critical step in the process remains image acquisition. “Multiparametric” MRI refers to the combined anatomic and functional phases obtained, which are: T2-weighted (T2W) anatomic sequences (T1 is also used as described later), diffusion-weighted imaging (DWI), and dynamic contrast-enhanced (DCE) sequences (Figure 130.1) [2]. Magnet strength is either 1.5 or 3.0 tesla (T), with higher field strengths generally allowing for higher signal-to-noise ratios and spectral resolution, potentially facilitating higher spatial resolution. A body surface coil must always be used during image acquisition; although the images can be further augmented with an endorectal coil, this is not required [3]. The advantages of endorectal coil use are improved scan quality and improved PCa staging [3]. Yet coil use comes with associated costs, namely increased time of procedure, and significantly more patient discomfort. Dual coil use (surface and endorectal) has been shown to have a sensitivity of 76% and a positive predictive value of 80% for PCa detection, as compared to surface coil alone with a sensitivity of 45% and a positive predictive value of 64% [4].

Image interpretation relies on findings noted in corresponding locations across mpMRI sequences that

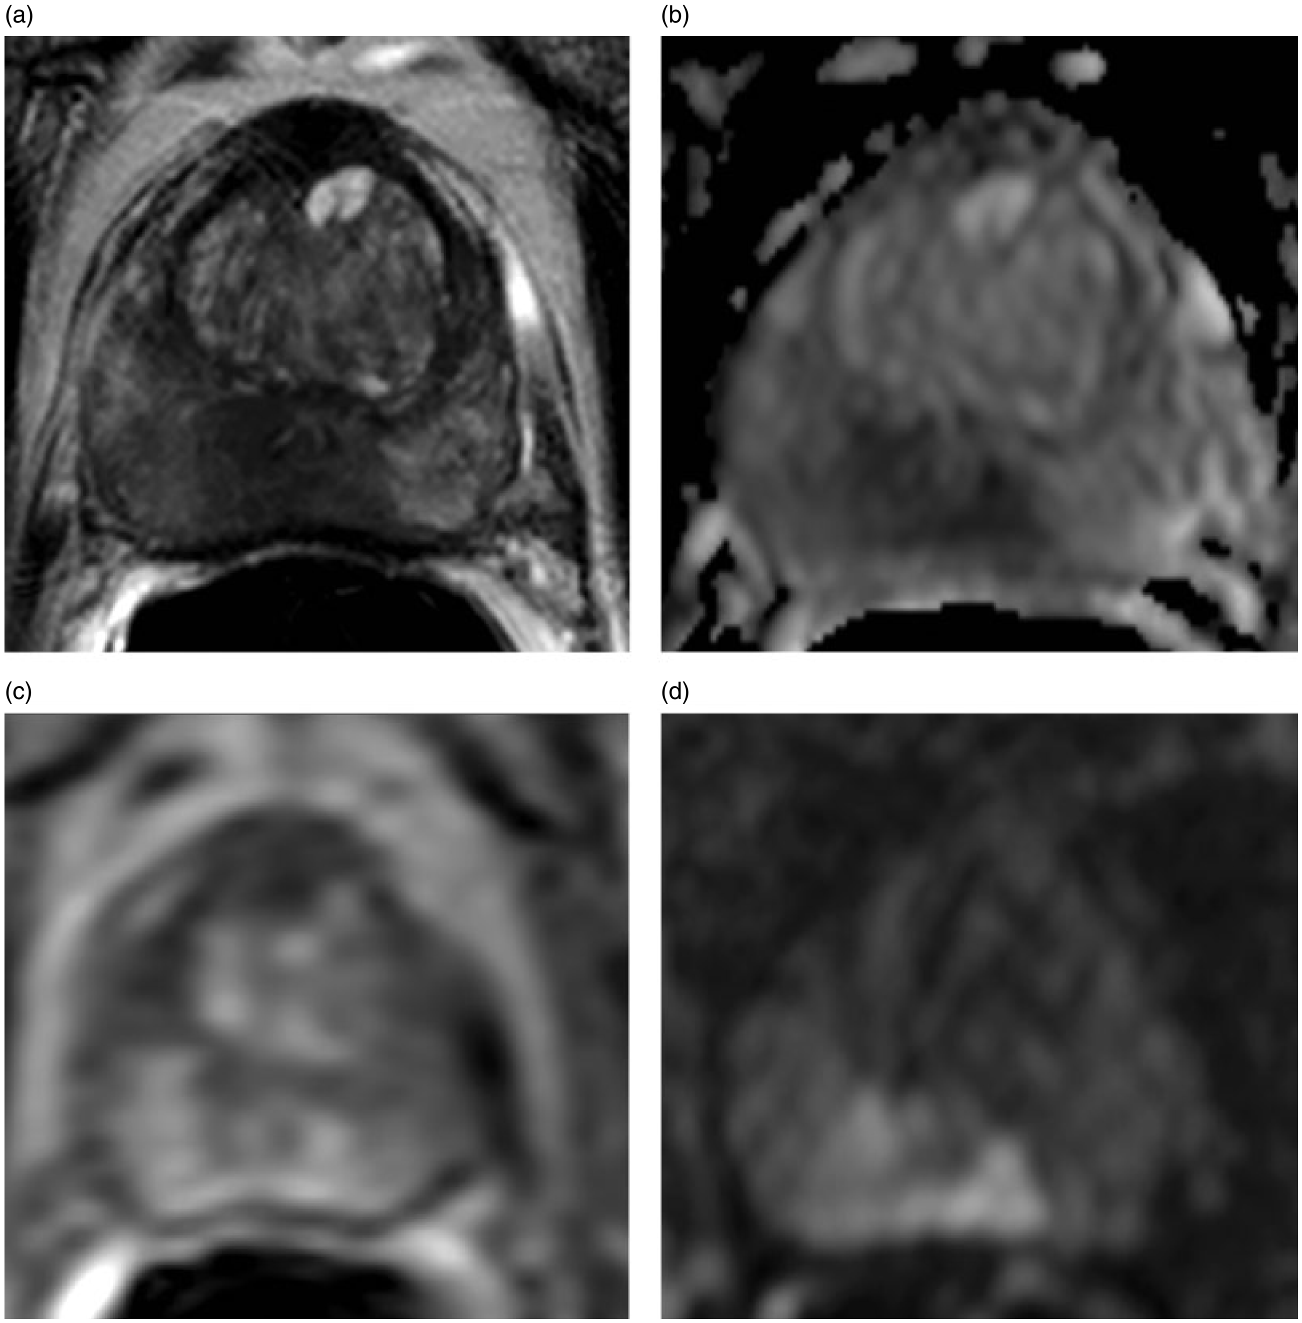

**Figure 130.1** Representative multiparametric MRI images. (a) T2-weighted axial; (b) apparent diffusion coefficient maps of diffusion-weighted imaging; (c) dynamic contrast-enhanced; (d) high *b*-value diffusion-weighted imaging. Patient was 66 years old, PSA of 14.61, and history of negative standard biopsies. A large lesion is seen in the right to midline mid-base peripheral zone (2.5 cm). This lesion has slight capsular bulge and a broad capsular base but no direct extracapsular extension. Seminal vesicles (SV) show possible invasion. Fusion-guided biopsy confirmed Gleason 4 + 5 (9), with SV invasion.

are integrated to provide a diagnostic impression [5]. T1-weighted imaging, which is a basic pulse sequence that produces images in which water-filled compartments are hypointense, is used to detect prior biopsy-related residual hemorrhage that may obscure suspicious lesions. T2-weighted imaging defines organ architecture, including the peripheral (PZ) and transition zones (TZ), as well as the central gland (CG), urethra, seminal vesicles, and capsule. Lesions suspicious for PCa appear darker in the PZ compared to normal tissue; by contrast in the TZ lesions will be hypointense and more heterogeneous [3].

DWI is a measure of the ability of water to diffuse freely within the organ. PCa lesions do not adhere to typical prostate architecture, with closer arrangement of cells and denser stroma. Thus the apparent diffusion coefficient (ADC) map, which is a display of ADC values for each voxel of an image, is lower for PCa lesions than for normal prostate parenchyma. “High *b*-value” images, which use *b*-values of ≥1400 s/mm$^2$, can also be used to attempt to improve the detection of clinically significant PCa via identifying significant restriction of movement and thus lesions will appear bright/hyperintense [3]. The amount of diffusion restriction has been associated with PCa grade and reflects the biological aggressiveness of the lesion [3].

The final sequence is DCE. This is obtained through the venous injection of gadolinium-based contrast, with scanning taking place before, during, and after administration. T1 sequences are used to detect the speed with which contrast arrives at the lesion, reflecting hypervascularity. Focal early hyperenhancement and early washout of the lesion implies malignancy, yet caution must be undertaken as benign conditions (BPH, prostatitis) may also produce similar findings. DCE has the most utility in the setting of recurrent PCa after definitive surgical, ablative, or radiotherapy [3].

mpMRI imaging is sensitive for the detection of clinically actionable, aggressive, PCa. Although each parameter has its own sensitivity and specificity, a meta-analysis of combined mpMRI has a sensitivity of 0.74 (95% confidence interval (CI) 0.66–0.81), and a specificity of 0.88 (95% CI 0.82–0.92) [6]. Correlation with pathology has shown a positive predictive value of 98–100% in detecting PCa [7]. Furthermore, mpMRI-TRUS FBx has been shown to be less sensitive for detecting low-risk lesions, a potential advantage that may be exploited to avoid overdiagnosis of clinically indolent disease [8].

Once the MRI is completed, postprocessing of images is performed to delineate the borders of the prostate, suspicious lesions, assign suspicion scores to each lesion. Suspicion scores reflect the likelihood that clinically significant cancer is present. Although multiple scoring systems have been developed (Likert, NIH scoring system), a consensus has arrived via the Prostate Image Reporting and Data Systems version 2.0 (PI-RADS 2.0) to standardize image interpretation and reporting [3]. Lesions are scored from 1 to 5 based on the number and severity of imaging findings (Figure 130.2). Increasing scores have been demonstrated to be associated with increasing detection of clinically significant PCa [9]. Due to the respective cancer diagnostic yield, recent recommendations advise lesions scored 1 or 2 do not need biopsy, while 4 or 5 do require biopsy. A suspicion score of 3 may require biopsy based on clinical findings [10]. The score assignment is different based on the anatomic area (PZ vs. TZ). Scores for the various parameters are based on lesion size, hypo/hyperintensity (based on location and parameter), heterogeneity, and morphology (Figure 130.2).

## Magnetic resonance–transrectal ultrasound fusion-guided biopsy

Two major FBx techniques exist: cognitive fusion and mpMRI-TRUS FBx. “In-gantry” MRI biopsy is a targeted biopsy method that was initially employed; the patient is sedated and scanned within the MRI apparatus during sampling; thus this method is time consuming, costly, and requires special equipment. Because of this it is not feasible for broad use. Cognitive fusion is where the surgeon interprets the MRI and attempts to mentally target, on ultrasound, a lesion identified on MRI. Although the literature is not in full agreement, cognitive fusion is heavily operator dependent and requires extensive knowledge of prostate anatomy and image interpretation [11]. We focus this chapter on the mpMRI-TRUS FBx method. This method and its delivery platforms have two distinct advantages: (i) targeted biopsy based on imaging; (ii) tracking of biopsy needle trajectories for repeat biopsies and management planning (i.e. surgical/focal therapy planning based on lesion location). These systems semi-automatically merge the real-time TRUS image to the preanalyzed MRI, and allow for targeting of lesions and storage of biopsy needle trajectory.

### Indications for fusion biopsy

There are recently described defined indications for the use of mpMRI and FBx in the management of PCa; however, the use of this novel technology is still an active area of research and its indications are evolving and expanding rapidly. Currently four potential clinical scenarios for using mpMRI-TRUS FBx exist and have been recently described in the National Comprehensive Cancer Network Guidelines:

#### Biopsy-naive patient who has suspicion of PCa

This indication describes using mpMRI in the initial workup of a patient who may have PCa, but has yet to be worked up and diagnosed by a urologist [12]. This is an area of great interest with a limited but growing body of data to support the use of mpMRI-TRUS FBx in the initial biopsy setting. Pokorny et al. published a report in 2014 which found that mpMRI-TRUS FBx, when performed in men with suspicious mpMRI lesions, increased the detection of intermediate/high-risk PCa by 17.7%, while concomitantly reducing the detection of low-risk PCa by 89.4% as compared to standard TRUS biopsy

DWI, diffusion-weighted imaging; ADC, apparent diffusion coefficient; T2W, T2-weighted; BPH, benign prostatic hyperplasia.

(SBx) alone [13]. In contrast, Tonttila et al. published a randomized control trial of 130 men comparing SBx to mpMRI and cognitive FBx, and found that FBx did not improve PCa detection [14]. Using the Artemis (described later) mpMRI-TRUS FBx system Mendhiratta et al. found in a cohort of biopsy naive men that mpMRI-TRUS FBx detected more Gleason Score (GS) ≥7 PCa than SBx ($P = 0.037$), and that most of the PCa found by SBx was low risk [15].

### Continued suspicion of PCa despite a prior negative TRUS biopsy

This indication is for using mpMRI-TRUS FBx to identify areas that may have been missed or undersampled during an initial SBx. A common presentation is a patient who has a rising PSA in light of a totally negative initial TRUS-guided biopsy [10]. Anatomic areas that mpMRI-TRUS FBx has shown utility for PCa detection include the anterior prostate [16], distal apex [17], and subcapsular prostate [18]. Vourganti et al. reported in 2013 that mpMRI-TRUS FBx discovered PCa in 37% of men who had a prior negative SBx, and that 11% had high-grade (≥GS 8) PCa that went undetected on SBx conducted at the time of FBx [19]. To investigate whether repeat standard biopsy is needed at the time of mpMRI-TRUS FBx, Salami et al. found in 2015 that FBx was more likely to identify clinically significant (GS ≥7, or GS 6 with >2 cores positive and/or >50% of any core involved) PCa as compared to standard biopsy ($P < 0.001$), but that SBx may be needed at mpMRI-TRUS FBx to avoid missing the 3.5% of clinically significant PCa that these authors found [20]. Sonn and colleagues published a series in 2014 of 105 men undergoing mpMRI-TRUS FBx for continued suspicion of PCa. They found that mpMRI-TRUS FBx, as compared to SBx, detected 1.4 times as many clinically significant PCa lesions [21].

**Risk stratification in active surveillance**

This indication implies using mpMRI in the active surveillance (AS) setting, whereby patients may be followed with serial PSA, DRE, mpMRI, and biopsy in various combinations and time frames to follow the patient [22, 23]. Specifically, mpMRI-TRUS FBx has utility in patients on AS with rising PSA or concern regarding lesion location (i.e. anterior lesion) and during confirmatory biopsy to establish candidacy by overcoming sampling error. An early report in 2013 by Stamatakis et al. found that imaging factors (lesion number, density, and highest lesion suspicion score) were significantly associated with patients being reclassified as not meeting AS criteria upon confirmatory biopsy [24]. Along this vein, Hu et al. investigated reclassification upon confirmatory re-biopsy using mpMRI-TRUS FBx and found that lesion suspicion score on mpMRI was associated with reclassification ($P = 0.001$), and that men with high-suspicion targets were three times more likely to be reclassified ($P = 0.006$) [25]. To investigate whether serial mpMRI scans have utility in predicting pathologic progression from GS 6 disease, Felker and colleagues studied 49 men over time and found the sensitivity and specificity of mpMRI for predicting progression to be 37% and 90%, respectively [26]. Their data suggest that mpMRI has a low false-positive rate and they concluded that mpMRI added incremental value when combined with clinical factors (core length and PSA density) for predicting progression. A recent report by Ma et al. evaluated the utility of mpMRI-TRUS FBx in AS and concluded that, given the relatively low sensitivity of mpMRI-TRUS FBx alone, a SBx should also be performed in the AS setting [27].

**Biochemical recurrence after definitive therapy**

After definitive therapy, a rise of PSA implies biochemical recurrence (definitions of which vary based on definitive treatment modality); mpMRI has been shown to have utility in identifying the recurrence. Specifically, Ho et al. demonstrated that combining mpMRI characteristics with clinical parameters had value in predicting biochemical recurrence as compared to clinical factors alone [28]. A study by Park and colleagues recently published using PI-RADS v2 scoring on mpMRI to predict biochemical recurrence found that PI-RADS suspicion score was the only parameter (among clinical, imaging, and pathologic parameters) that was an independent predictor of biochemical recurrence on multivariate analysis [29].

## mpMRI-TRUS FBx workflow

As briefly described earlier, the mpMRI-TRUS FBx workflow includes the following steps, carried out in sequence: MRI acquisition and analysis, ultrasound imaging at the time of biopsy, MRI-TRUS image co-registration, and targeted sampling (Figure 130.3).

### Image segmentation

The prostatic border is "segmented" or contoured using imaging software on serial T2-weighted axial slices. Similarly, each lesion may be contoured to provide a rendered lesion volume or a single slice selected to provide a centroid point. Thus, targets are defined as volumes or center points on the corresponding T2-weighted image. The calculated prostate volume (based on segmentation) and targets are superimposed on the T2-weighted images, and then are uploaded to the biopsy workstation.

### TRUS sweep and 3D ultrasound volume construction

At the time of biopsy, a three-dimensional (3D) TRUS volume of the prostate is constructed using stacking two-dimensional slices acquired during a prostate sweep using the TRUS probe. The TRUS prostate model undergoes semi-automatic segmentation by a software algorithm and the performing physician can manually adjust the borders. The 3D TRUS volume is "fused" or co-registered to the MRI images to allow for real-time targeting during FBx (Figure 130.3) [30]. Internal landmarks (cysts, calcifications, etc.) may be used to optimize co-registration. Furthermore, the pressure on the TRUS probe can be altered to ensure parallel deformations noted during MRI image acquisition (generally due to the endorectal coil).

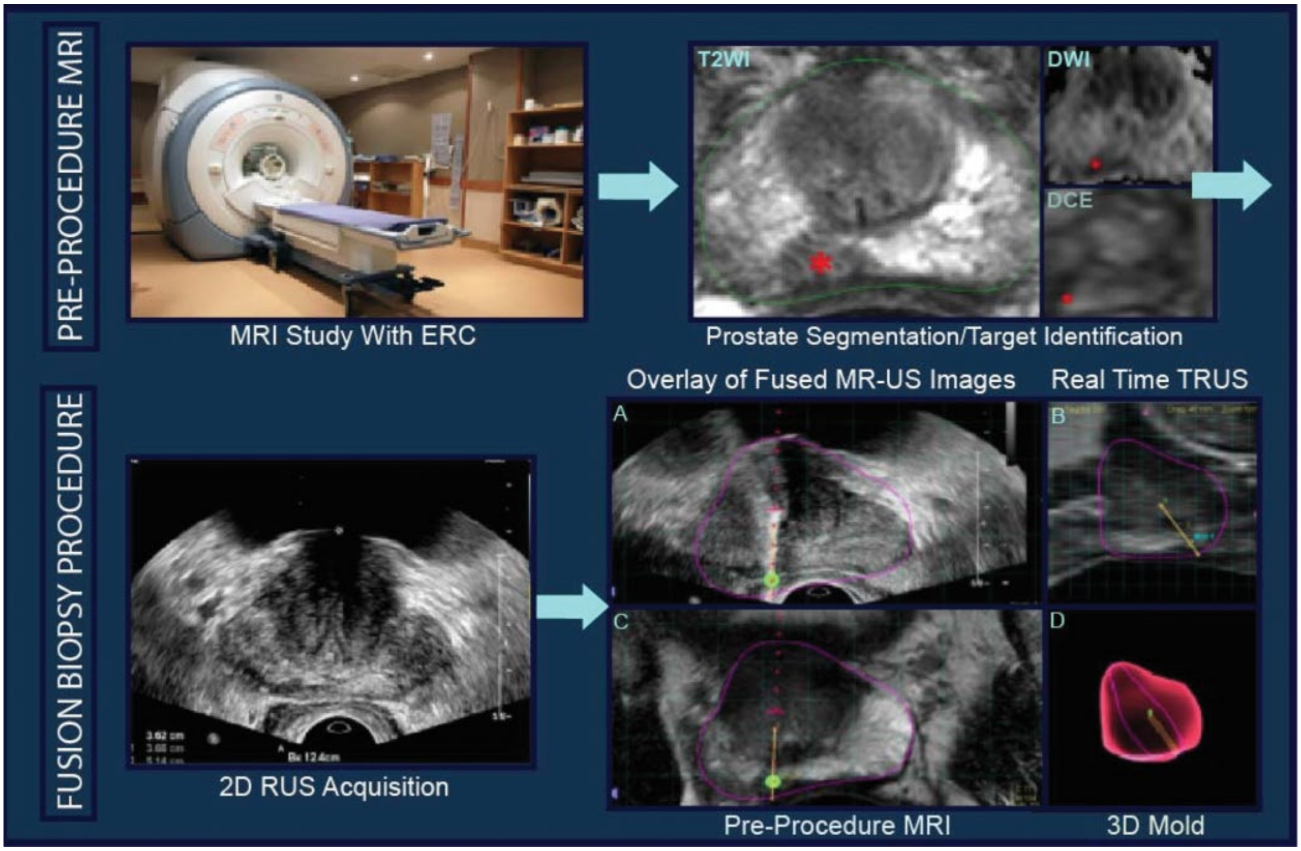

Figure 130.3 Workflow for mpMRI-TRUS FBx. The main steps include MRI acquisition and analysis (segmentation and defining lesions). The transrectal ultrasound (TRUS) sweep is performed at the time of biopsy and the preprocedure MRI images are "fused" to the live TRUS images.

Registration is conducted by computer software driven algorithms. There are two main algorithms for registration: rigid and elastic.

## Image registration and biopsy

With the rigid registration, the unaltered surface edges of the prostate from the MRI and the ultrasound rendered images are used; the two images are aligned via translational or rotational adjustments to allow the algorithm to most accurately merge the images. Rigid registration allows the internal geography of the organ to be preserved in the fused image; the drawback is that the two images and thus targets may not align completely. By contrast, the elastic registration algorithm transforms the 3D MRI volume such that the MRI prostate contours are force-fit to the 3D ultrasound-derived volume. It follows, therefore, that with elastic registration, internal prostate geography may be distorted while the contours are preserved. It is critical with elastic registration that the TRUS sweep and 3D construction is very accurate to avoid misalignment. Increasing the number of transformations potentially allows for error to be introduced at each step; however, platforms that utilized both rigid and elastic registration have demonstrated high degrees of accuracy.

Operators can check the registration via the platform-specific user interface; typical examples are co-display of MRI and TRUS image data with the ability to blend MRI and ultrasound or having the fused images displayed side-by-side. If registration is suboptimal, manual adjustments to the segmentation and registration by the operator can be conducted prior to tissue sampling. Fusion platforms exist that allow for both transrectal and transperineal approaches (see specific commercial systems later). For transrectal biopsy, the patient is placed in the left lateral decubitus position, or in lithotomy for transperineal sampling (Figure 130.4). Antibiotic prophylaxis conforms to the American Urological Association's best practice policy statement on urologic surgery antimicrobial prophylaxis [10].

## Biopsy needle navigation and mapping

For the fusion platforms to function properly, the real-time position of the biopsy probe and needle in 3D space must be monitored so to guide the user to the image defined targets. This will be discussed in-depth here with the specific commercial systems. Regardless, such monitoring is needed to carry out the other major functions of mpMRI-TRUS FBx: navigation and mapping.

Navigation or tracking describes the mpMRI-TRUS FBx system, guiding its user toward the target lesion in real time by determining the probe or needle real-time location in 3D space. The live TRUS images with the overlaid mpMRI information direct the operator to the lesion location for biopsy needle deployment. Once the needle has been deployed and the biopsy tissue obtained, mapping describes the various mpMRI-TRUS FBx system's capabilities to record the location of the biopsy needle using the MRI as the "map" (Figure 130.5). Biopsy core trajectories may be overlaid. This map can be stored

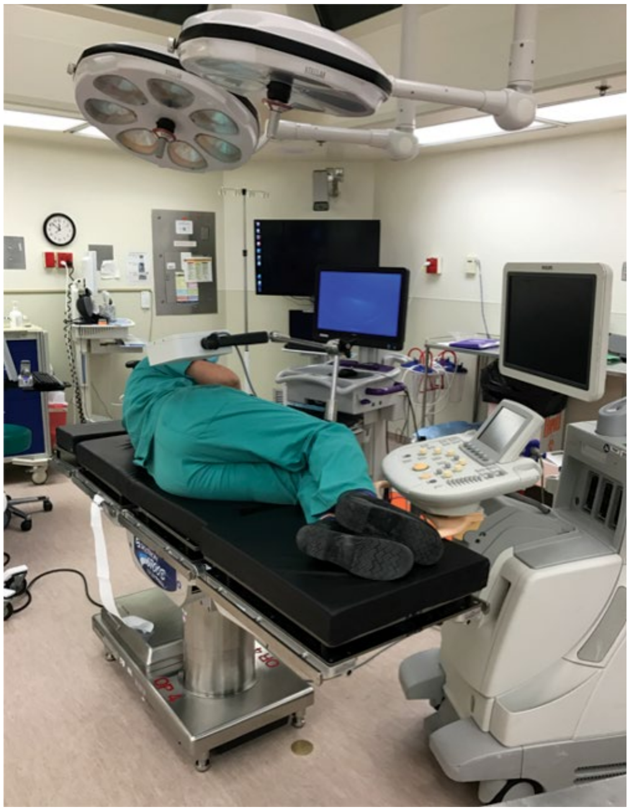

**Figure 130.4** Patient positioning. The patient is typically in in the left lateral decubitus position with the urologist stationed posterior to them.

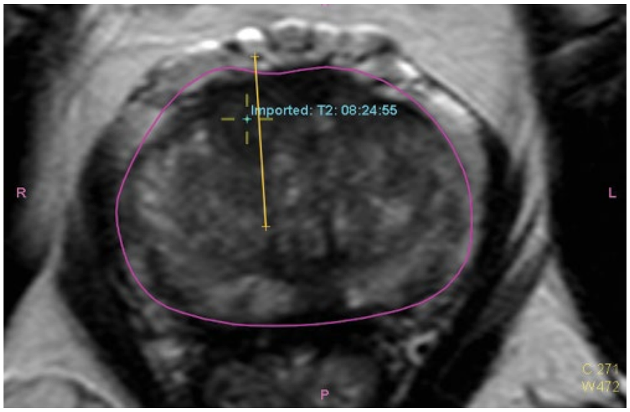

**Figure 130.5** Mapping. This is an example image from the UroNav system of a segmented (purple outline) prostate and the mapped needle trajectory (yellow line) overlaid on the MRI image.

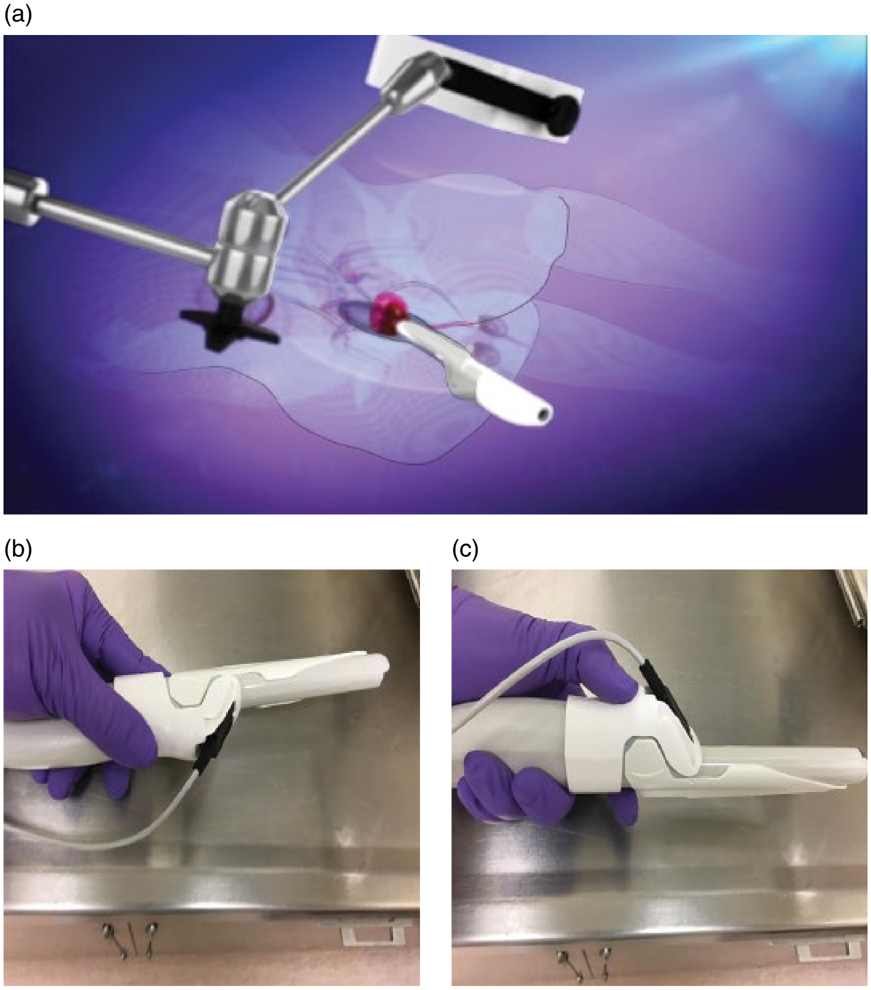

**Figure 130.6** Tracking. (a) Positions of the electromagnetic field generator and the biopsy probe that allow for the tracking function. (b,c) A UroNav biopsy probe with electromagnetic tracker clipped to its custom sheath along with needle guide.

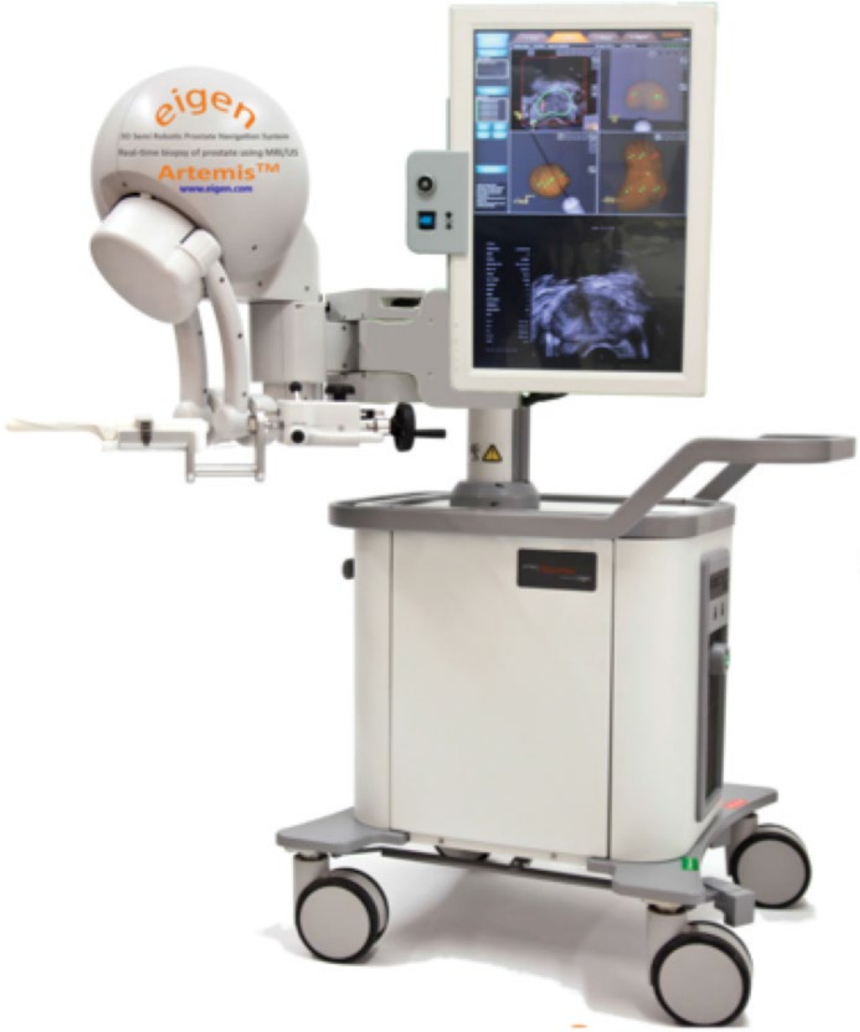
on the system for later use to resample areas of interest such as in AS. If all cores are mapped, a systematic core that is positive may be recalled despite no lesion being visible on MRI [31].

There are three main methods of needle tracking: electromagnetic tracking; position-encoded joint tracking (built within robotic arm of a system); and TRUS-TRUS tracking.

Electromagnetic tracking is performed by affixing a sensor to the TRUS probe which, when positioned in an externally produced magnetic field (typically an electromagnetic field generator that can be positioned above the patients' pelvis at the time of biopsy), can relay the position of the sensor in real time to the FBx platform (Figure 130.6). The signal is then converted by the platform software to a 3D spatial position. This allows the user to approach target lesions in real time using the freehand TRUS probe. A drawback is the potential for human error due to movement at the time of biopsy needle deployment [32]. This kind of tracking is found in the UroNav (In Vivo, Gainesville, FL, USA), Real-Time Virtual Sonography (Hitachi, Tokyo, Japan), and Virtual Navigator (Esaote, Genoa, Italy) platforms.

In contrast to the freehand TRUS-based FBx platforms, other systems utilize robotics to target lesions. Such systems contain self-articulating arms with built-in positional angle-sensing encoders, which control the TRUS probe's movement toward the image-based target (Figure 130.7). This tracking system is called position-encoded joint tracking. These systems continuously measure the sensor to assist the user with obtaining the correct biopsy angle and probe position for tissue sampling as they move the arm toward the target [33]. They do allow the user some probe manipulations: the degrees of freedom are typically forward/reverse and rotational. The benefit is stability and thus decreased mechanical biopsy error, as once positioned the probe will remain in place. The limited ability to review MRI images continuously during the procedure



eigen

and the tracking device's bulkier size are drawbacks for this modality [34]. The Artemis (Eigen, Grass Valley, CA, USA), BiopSee (Pi Medical, Athens, Greece), FusionBx System (Focal Healthcare, Toronto, Ontario, Canada), and Biojet (BK Ultrasound, Peabody, MA, USA) platforms utilize this tracking modality.

Lastly, TRUS-TRUS registration and tracking system is found in the Urostation (Koelis, Grenoble, France) platform. After the initial 3D TRUS sweep of the prostate and 3D ultrasound construction, a second TRUS sweep and second 3D TRUS reconstruction and registration is conducted prior to each biopsy needle deployment. Elastic registration of the real-time 3D TRUS volume is co-registered to MRI images allowing for the identification of isoechoic lesions. However, this system does not track the probe in real time. The user must review needle core locations after sampling, which may introduce error if the probe is moved between the prebiopsy scan and core sampling.

## Commercial mpMRI-TRUS FBx systems

The remainder of this chapter will review the various commercial mpMRI-TRUS FBx platforms: their workflow, strengths and weaknesses, and data pertaining to the specific platform. It is important to note that this field is evolving rapidly and that each system was developed in a specific context (i.e. some systems can only conduct rigid or elastic registration). Because of this, the data for each system reflect the context of that system's development and many have evolved since their inception.

Please refer to Figure 130.3 for a general overview of the FBx workflow; under each system we will highlight features of that system's unique workflow.

## UroNav

The UroNav platform was developed through a collaboration of academia and industry (National Institutes of Health and Philips/In Vivo Healthcare) and was approved by the US Food and Drug Administration (FDA) in 2006. This system is adaptable to different ultrasound manufacturers and MRI/imaging systems. It includes both elastic and rigid registration capabilities. UroNav utilizes electromagnetic tracking and freehand TRUS ultrasound methodology. A transperineal platform was recently introduced.

The workflow for this system starts with acquiring mpMRI images, radiological segmentation/lesion marking, and uploading of the MRI to the platform workstation. At the time of biopsy, the electromagnetic field generator is stationed above the patient's pelvis to afford probe tracking. The ultrasound sweep of the prostate is then conducted, allowing the software to construct a 3D ultrasound prostate volume. This 3D TRUS prostate is segmented by the UroNav software (with user adjustments as needed). The user can also adjust the image registration after segmentation. At this point, the user can proceed with the targeted biopsies as the targets are shown as multicolored "bullseyes" on the fused images of the UroNav display. The navigation software assists in guiding users to the target until the tracked needle guide is in-line with the target. Insertion of the needle to the proximal lesion edge ensures that the biopsy will be of the correct trajectory. Biopsies can then be taken in both the axial and sagittal planes [35]. Mapping of needle core trajectories can be stored by the user.

In a landmark paper from 2014, Siddiqui et al. studied 1003 prospectively enrolled men and showed a 30% increase in the detection of high-risk cancers compared to SBx [8]. Furthermore, mpMRI-TRUS FBx detected 17% fewer low-risk cancers. This finding was validated by Rastinehad et al. in a propensity-matched cohort who found a durable, statistically significant difference in PCa detection rate using mpMRI-TRUS FBx as compared to TRUS-guided biopsy alone [36]. One question that arises regarding these systems is their accuracy, a question addressed by Xu and colleagues [37]. They showed that the error of UroNav is 2.4 ± 1.2 mm based on phantom studies.

## Real-Time Virtual Sonography and Virtual Navigator

These general-purpose fusion systems (Real-Time Virtual Sonography, Hitachi, Japan; Virtual Navigator, Genoa, Italy] were originally designed to merge TRUS images to a multitude of different imaging modalities (CT, MRI, etc.). They are similar in workflow to the UroNav method described above: mpMRI images are obtained, segmented, and then registered with real-time TRUS at the time of biopsy. An electromagnetic amplifier is placed above the patient to facilitate needle tracking. Both of these systems use a freehand TRUS probe.

The data for using these platforms in mpMRI-TRUS FBx are more limited. In 2010, using Real-Time Virtual Sonography, Miyagawa et al. found that this platform, used transperineally, in a cohort of 85 men with continued suspicion for PCa, was superior to random TRUS biopsy on a per-core analysis for detecting PCa (32% (67/192) vs. 9% (75/833) cores, $P < 0.01$) [38]. Delongchamps et al. found in 2013 that using Virtual Navigator for mpMRI-TRUS FBx detected a significantly higher amount of PCa relative to systematic biopsy in 131 men who were evaluated for PCa ($P = 0.0065$) [39].

## Artemis

This platform marks the delineation between the freehand TRUS probe systems and the mechanical position encoders. Within the joint of each arm of the Artemis platform are built special angle-sensing encoders (Figure 130.5). Artemis (Eigen, Grass Valley, CA, USA) was approved in 2007 by the FDA. This system is able to function with several different ultrasound and MRI/imaging systems, uses elastic registration, and does not require an electromagnetic field generator.

For Artemis, the workflow begins in a familiar manner with mpMRI acquisition and radiological segmentation. At the time of biopsy, using the robotic mechanical arm, an initial prostate sweep is obtained to form the ultrasound 3D prostate model. As with the freehand systems, software will automatically segment the ultrasound-based model, with manual adjustments made as needed. After registration, Eigen navigation software guides the user-driven biopsy needle to the predefined MRI targets. Mapping functionality can record the location of obtained cores. Given the differences in this system from traditional freehand biopsy, there is a learning curve to effective utilization of the platform. However, once an operator becomes experienced, the system yields highly precise reproducible biopsies that minimize human error.

In 2015, Meng et al. published a series of 601 men that found that mpMRI-TRUS FBx detected more PCa with a GS ≥7 and less PCa of GS 6 than standard biopsy ($P < 0.001$) [40]. Furthermore, they found that mpMRI-TRUS FBx identified greater numbers of PCa with a GS ≥7 as compared to standard biopsy in men with no prior biopsy ($P = 0.012$), a prior negative biopsy ($P = 0.010$), and a prior PCa diagnosis ($P = 0.043$). Filson et al. studied 1042 men prospectively and found a 35% detection rate for clinically significant (GS ≥7) PCa and that 20% of patients with a negative MRI had GS ≥7 [41]. In agreement with prior findings, they found that the combination of mpMRI-TRUS FBx and standard biopsy resulted in increased clinically significant PCa detection. This system has proven its biopsy error rate to be 1.2 ± 1.1 mm [34]. This error rate is smaller than the freehand systems and may be attributable to the unique stability of the mechanical arm.

### Biojet

This system also uses a mechanical arm with angle-sensing encoders for TRUS probe tracking, similar to the Artemis system. Biojet (BK Ultrasound, Peabody, MA, USA; DK technologies, Barum, Germany] is unique in that it is capable of being used either transrectally or transperineally. This system utilizes rigid registration only. The workflow of this system is similar to the Artemis system. In 2015 in a small prospective study of 20 patients performed by Shoji et al. showed that Biojet detected PCa at significant higher levels compared to systematic biopsy (31.8% (14/44) vs. 6.7% (16/240), $P < 0.0001$) [42].

### Biopsee

In contrast to the mechanical articulating arms of Artemis and Biojet, BiopSee (Pi Medical, Athens, Greece) uses a bidirectional stepper that is affixed to the operating room table. This gives the system more precise control of the TRUS probe. Notably, this system is intended for transperineal biopsy. The probe is affixed to the stepper, into which encoders are embedded. These are used to monitor probe position (depth and rotation are the monitored parameters). This system utilizes rigid registration.

Although intended for transperineal biopsy, the workflow for this system is similar to those described earlier. mpMRI imaging is obtained, the prostate segmented, and lesions marked by the radiologist. On the day of biopsy, a sweep of the prostate is conducted to generate a 3D ultrasound model. The 3D TRUS model is rigidly registered to the MRI. From there the fusion biopsy is performed. There is, however, a caveat of a learning curve, not only for using the mounted probe, but also for the transperineal component. This may add time to this mpMRI-TRUS FBx procedure. Kuru et al., in 2013, showed that in 347 men cores obtained through the BiopSee targeting system detected statistically significant more PCa than systematic biopsy (30.0% (386/1281) vs. 8.2% (523/6326), $P = 0.01$) [43].

### Urostation

In contrast to the other commercial systems described, Urostation (Koelis, Grenoble, France) utilizes a novel TRUS-TRUS image registration algorithm for needle tracking. It is a freehand probe system that, since it only utilizes TRUS and mpMRI, does not require additional costly hardware such as field generators or FBx-specific hardware. Of particular note is the fact that the TRUS-TRUS registration is used to retrospectively determine needle position on an mpMRI obtained prior to biopsy.

In terms of workflow, the methodology leading up to biopsy is unchanged from the other platforms. Once the MRI is obtained, segmented, and lesions demarcated, the patient is brought for biopsy. A 3D TRUS prostate model is obtained via a probe sweep. It is at this stage that the workflow diverges from other systems. The initial 3D TRUS model is registered to the MRI elastically. As each biopsy core is obtained, another 3D TRUS model is constructed with the needle deployed into the lesion. This is registered to the initial 3D TRUS model to confirm correct needle placement. This distinct exercise is conducted sequentially for all lesions. In order for the imaging of the deployed biopsy needle to be accurate, the user must hold it in place for 3–5 seconds. In 2012 Rud and colleagues retrospectively investigated the PCa detection rate in 90 men and found it to be 52% (60/115) using Urostation [44]. Expanding on this Mozer et al. included 152 men and found that Urostation detected a significantly higher proportion of men with clinically significant PCa (43/152 vs. 37/152, $P = 0.03$) [45].

## Discussion and conclusion

Currently, the gold standard for pathologic confirmation of PCa remains TRUS biopsy. However, mpMRI-TRUS FBx has served to bridge the gap of inherent limitations in nondirected sampling. Though not without its shortcomings, this technology has seen significant uptake in a short period of time and outcomes from expert centers have been reproducible when implemented thoughtfully [36]. The development of FBx holds the potential to completely shift the paradigm of PCa diagnosis and management. It offers more accurate biopsy of targetable lesions that has been shown to improve the diagnosis of clinically significant PCa while avoiding the detection of indolent disease [46]. For patients who harbor MRI-visible lesions, current practice remains the inclusion of both targeted and systematic biopsy, as even at expert centers MRI can miss up to 20% of clinically significant prostate cancers [20, 41].

This technology has broad applicability across the spectrum of PCa care: diagnosis, AS, staging, surgical planning, and local recurrence after whole-gland or focal therapy. Widespread adoption must, however, be balanced with judicious use as the cost is not nominal. In addition, implementation must be performed responsibly and conscientiously. Achieving an optimal outcome requires a multidisciplinary approach, as the entire process is dependent on seamless interaction between radiologists and urologists. In addition to high-quality imaging, there exists a learning curve to both prostate mpMRI interpretation and FBx that must be overcome for accurate, reproducible, and reliable results.

Introduction of this technology into the broader urologic community is another area that needs further evaluation. Cost-effectiveness in a variety of settings is a concern given the requirement for imaging and additional hardware costs for biopsy. Early cost modeling has demonstrated mpMRI-TRUS FBx does not add additional cost to the current standard of care workup [47]. As the majority of information from imaging is gleaned from T2-weighted images and DWI, there is support for biparametric MRI as a potential intermediary step after PSA screening but prior to biopsy [12]. The potential of using a "screening MRI" (forgoing the time and cost of using contrast) is one way in which the urology community is trying to adapt to decrease cost, and broaden mpMRI-TRUS FBx use. One must also keep in mind the learning curve for a new skillset and the need for support and integration of our colleagues in other specialties when incorporating this novel technology into an existing practice. Overall, mpMRI-TRUS FBx is a novel technique that allows the urologist for the first time to visualize and target-specific lesions within the prostate while still using real-time ultrasound imaging at the time of biopsy. As the urology community continues to advance our knowledge of this platform's utility, the ability to provide targeted, precision care for our patients will also improve. Because of this, better patient selection and risk stratification will translate to superior oncologic outcomes.

# Focal Therapy of Prostate Cancer

*Kae Jack Tay & Thomas J. Polascik*

*Duke Comprehensive Cancer Center, Duke Cancer Insititute, Duke University, Durham, NC, USA*

## Introduction

The global incidence of prostate cancer is estimated at 30.6 per 100 000 per year and is the second most incident cancer among men [1]. In the United States, it is the most common solid organ malignancy among men and the third leading cause of death [2]. Much controversy has arisen regarding prostate cancer overdiagnosis and overtreatment that are thought to have exposed many men to the side-effects of traditional radical treatments. Although these treatments have been oncologically effective they often result in collateral damage to the surrounding cavernosal nerves, urinary sphincter and other adjacent organs [3]. Tools for early detection of prostate cancer such as multiparametric magnetic resonance imaging (mpMRI) and MRI-fusion targeted biopsies, as well as recognition of Gleason grade 4 and 5 cancers as the subset of cancers which are biologically lethal, have led to an interest in gland-sparing targeted therapies with less morbidity [4].

## Historical perspective

The idea of prostate focal therapy was borne out of the successful paradigm shift from the Halsted mastectomy to local excision for breast cancer. Early attempts in prostate gland-sparing treatments involved subtotal ablations, whereby the sparing of one, or possibly both, neurovascular bundles was attempted [5]. Later, the term “male lumpectomy” was coined to describe hemi-ablation of the prostate as the first form of focal therapy [6, 7]. Today, advances in technology have allowed surgeons to better visualize the prostate and localize cancer, and has made possible true image-guided focal destruction of the offending cancer with a margin of normal tissue.

## Concepts in focal therapy

At an early stage of prostate cancer, malignant foci may be localized to a few discrete areas of the prostate. If these could be eradicated without harming the remainder of the prostate gland, collateral damage to the cavernosal nerves, urinary sphincter or rectal wall could be minimized depending on the area(s) where the cancer is located.

## Index lesion

A developing concept in focal therapy is based on the finding that the natural history of prostate cancer is typically driven by a primary lesion, rather than secondary lesions [8]. Despite heterogeneity within primary lesions, the majority of metastatic prostate cancer has also been found to originate from a single precursor cell [9]. Karavitakis et al. analyzed 100 consecutive whole-mount radical prostatectomy specimens, finding that although tumors were often multifocal (78%) and bilateral (86%), the 100 index tumors identified invariably defined pathological features of the cancer and of 170 satellite tumors, 87% were low grade, and 99.4% less than 0.5 ml [10]. With the concept of the index lesion, if the dangerous foci in the prostate could be eradicated, oncological control of the cancer could be achieved while maintaining quality of life.

## The complementary roles of focal therapy and active surveillance

The last decade has seen many advances in the biological understanding of prostate cancer. Two of the largest active surveillance cohorts reached 10–15 years of follow-up, showing an extremely low metastasis rate among men with D'Amico low-risk prostate cancer [11, 12]. In one of the cohorts with an extended inclusion criterion with some men having Gleason 3 + 4 cancer, it was found that these men with intermediate-risk cancer formed the majority of those in whom cancer progressed [13]. In the randomized Prostate Intervention Versus Observation Trial (PIVOT), although overall survival benefit was not seen, there was a survival benefit in the intermediate-risk subgroup with prostatectomy rather than observation [14]. Indeed, Gleason grade 4 cancers appear to have many more hallmarks of cancer compared to Gleason grade 3, and likely represent the relevant therapeutic target [15].

These findings have led to interest in a complementary strategy whereby intermediate- or high-grade cancer foci are eradicated with focal therapy, while the remainder of the gland with low-grade cancer remains on active surveillance [16]. During surveillance, if any higher grade cancers are detected they could potentially be treated focally again, with the aim of achieving long-term oncological control and effectively transforming prostate cancer into a chronic disease, commensurate with its long natural history.

To these ends, a successful focal strategy depends on a multidisciplinary team of prostate cancer specialists working on the following tenets:

- Accurate determination of disease extent/location through advanced imaging and biopsy
- Ascertaining that the patient will benefit from treatment and be compliant to follow-up
- Complete ablation of the index lesion(s)
- Posttreatment monitoring utilizing advanced imaging and biopsy with a view to future retreatments or conversion to whole-gland treatment, if necessary.

## Patient selection

Patient selection is the cornerstone of a successful focal therapy strategy. The approach is workable only if the extent of clinically significant cancer can be accurately ascertained. Once determined, the clinician will have to decide whether the cancer can be accurately targeted for complete eradication, using the guidance and available ablative technologies.

### Biopsy

The majority of biopsy-based patient selection studies were predicated on the use of hemi-gland ablations as the prototype form of focal therapy whereby it was important to determine whether cancer was unilateral or bilateral. At that time, many surgeons felt that focal therapy should be applied only in men with low-risk prostate cancer. Though this situation is less likely today, the data remain instructive on the ability of biopsy to map cancer. Barzell and Melamed first showed in a series of 80 patients that using an extensive transperineal mapping biopsy (TMB) as the gold standard, staging transrectal ultrasound-guided (TRUS) biopsies had a false negative rate as high as 47% and sensitivity and negative predictive value as low as 54% and 49% respectively in determining suitability for hemi-ablative cryotherapy [17]. In a slightly larger cohort of 110 men with unilateral cancer on TRUS biopsy, Onik and Barzell demonstrated that more than half were disqualified after undergoing TMB [18]. In a population of 538 men who had all undergone radical prostatectomy, Polascik et al. showed that biopsy unilaterality was the strongest predictor of pathological unilaterality with a sensitivity of 88.4%, specificity 34%, and positive and negative predictive values of 28% and 91%, respectively [19].

TRUS biopsy has served urologists well in the diagnosis of prostate cancer. However, in determining the true grade and extent of cancer, it is untargeted, suffers from inconsistency due to its random nature and may systematically miss anterior cancers due to preferential posterior zone sampling [20]. Nonetheless, Tsivian et al. showed that increasing the number of biopsy cores (sextent vs. extended) at TRUS biopsy was associated with a significant improvement in specificity (from 37.1% to 53.9%) and negative predictive value (from 91.8% to 95.8%) [21]. Moreover, if an increased burden is detected on TRUS biopsy (2 or less vs. more than 2 positive cores), Truesdale et al. found a greater likelihood of experiencing pathological persistence of cancer or biochemical recurrence after focal treatment [22]. Although a direct comparison was not available, Abdollah et al. showed that at 24-core TRUS biopsy, in predicting unilateral disease, specificity remained at 49.4% and positive and negative predictive values 22.6% and 98.9%, respectively, demonstrating the limitations in enhancing test performance by increasing the number of biopsy cores transrectally [23].

Using a combination of clinical parameters, Fu et al. attempted to identify a set of variables to predict unilateral cancer in a cohort of 1495 men, finding that only prostate specific antigen (PSA) ≤4 ng/ml and unilateral cancer on biopsy were significant factors [24].

On the other hand, Gallina et al. were unable to develop a model in a cohort of 321 men, finding only that the number of positive cores were significant with an area under the curve (AUC) of 0.52 [25]. The majority of the studies mentioned here had the objective of predicting low-risk cancer. With recognition that Gleason ≥7 cancers are the ones likely to drive progression, metastasis and mortality, contemporary interest resides in identifying these higher grade cancers rather than low-grade ones.

## Multiparametric MRI

Advances in MRI have re-ignited interest in focal therapy due to the possibility of image-based cancer mapping. mpMRI typically comprises T2, diffusion-weighted imaging (DWI) and dynamic contrast enhanced (DCE) imaging that preferentially detects higher grade prostate cancers and larger cancer foci [26, 27]. DWI relies on the relative ease of movement of water molecules. This is restricted in areas of increased cell density and may be directly related to the presence of histological high-grade cancer [28].

As an imaging modality, mpMRI has less bias toward any particular region of the prostate compared to TRUS biopsy and can be useful in the detection of anterior cancers. In a cystoprostatectomy series of 345 patients free from screening-related selection bias, Nevoux et al. identified 104 incidental prostate cancers, of which 33% were anteriorly located beyond the reach of an ordinary biopsy needle [29]. Among radical prostatectomy specimens, an incidence rate for anterior cancers of 15–21% has been reported [30, 31]. If detected at an early stage, anterior cancers could be treated with focal or zonal ablation, sparing the cavernosal nerves bilaterally and improving quality of life of men undergoing prostate cancer treatment [32].

Accurate staging is a critical component of identifying the ideal focal therapy candidate, especially with an emphasis on treating men with higher grade cancer. Using various inclusion criteria, contemporary mpMRI series report an accuracy of 62–74%, sensitivity of 35–63%, specificity of 73–91%, positive predictive value of 36–85%, and negative predictive value of 57–92% in the detection of extracapsular extension [33–37]. Gupta et al. evaluated 158 men who had undergone radical prostatectomy and found that mpMRI staging outperformed the Partin tables in predicting pathological extracapsular extension (AUC 0.88 vs. 0.70) [38].

However, mpMRI does have its limitations and should not be viewed as a panacea for patient selection. It remains important for urologists to "correlate clinically." mpMRI is subject to technical variability with differential performance between machines of different field strengths. For example, a magnetic field strength of 3 T improves spatial resolution and image acquisition times compared to that of a 1.5 T scanner by virtue of a better signal-to-noise ratio [39]. On the other hand, the signal from a 1.5 T scanner may be augmented by an endorectal coil (ERC) due to its proximity to the prostate [40]. Furthermore, a significant learning curve exists and an accurate interpretation is highly dependent on reader experience both in identifying cancer and detecting extracapsular extension [41, 42]. Standards in mpMRI interpretation with regards to cancer identification have recently been jointly promulgated by the European Society of Urology and Radiology (ESUR) and the American College of Radiology (ACR), culminating in the Prostate Imaging Reporting and Data System (PI-RADS) scoring system, which aims to alleviate inter-reader variability [43].

Jeong et al. reported on 574 men who underwent 12-core TRUS biopsy, 1.5 T mpMRI without ERC, and subsequent prostatectomy, finding that MRI contributed only marginally in predicting unilateral cancer [44]. On the other hand, Tran et al. reported that mpMRI read using PI-RADS, in combination with TMB, offered a negative predictive value as high as 91% in identifying hemi-prostates with clinically significant prostate cancer [45].

## Targeted/fusion biopsy

Visualization of the prostate using mpMRI allows urologists to perform targeted sampling of suspicious areas of the prostate to plan for focal therapy. MRI-TRUS fusion biopsy can be performed using visual estimation targeting (VET), otherwise known as cognitive/mental fusion, whereby the biopsy is performed using ultrasound guidance and the proceduralist estimates the position of the suspicious lesion. The alternative method is to use software fusion whereby the MRI image is fused to the ultrasound image using a variety of software algorithms and presents as an overlay on the ultrasound image for the proceduralist to target. In expert hands, VET can be as good as software fusion [46]. On the other hand, software fusion has a learning curve as well because the overlay of the MRI image onto the ultrasound image is often imperfect and the user has to adjust accordingly to achieve an accurate biopsy [47]. Ultimately, patients can only be identified accurately for focal therapy by an experienced multidisciplinary team of radiologists and urologists. Such a team who will mount the learning curve together is a critical component of a focal therapy program.

### Contemporary patient selection criteria

The majority of early studies in focal therapy included a majority of low-risk cancer patients. Similarly, many contemporary phase I/II trials regarding new techniques necessarily include patients who have low-volume, low- to intermediate-risk cancer. The ideal focal therapy candidate has been the subject of several expert consensus meetings. In general, there has been a shift in focus from eradicating all cancer to that only of clinically significant cancer. The findings of the consensus meetings are summarized in Table 131.1.

## Ablation patterns and current technologies

### Types of ablation

Many different ablation patterns have been termed focal therapy, leading to significant heterogeneity within the focal therapy literature. Some of these techniques, such as “hockey-stick”-type ablations, would be more appropriately classified under the umbrella term of partial prostate ablation (Figure 131.1). In an international consensus meeting on definitions in focal therapy, Postema et al. reported that focal therapy should include treatment of a lesion, quadrant ablation, and hemi-ablations [52]. Some authors would further argue that treatment of a lesion can be further classified into image-targeted lesion ablation versus non-image-targeted, whereby the lesion is treated based on biopsy information.

### Cryotherapy

Prostate cryotherapy has been the modality of choice for focal therapy in the United States [53]. It is usually performed using a transperineal approach, generally under ultrasound guidance though there are limited reports of in-bore MRI cryotherapy. Third-generation cryotherapy probes allow for an active freeze and thaw, and through variable ice length adjustment, allow conformation of the iceball to the desired shape of the planned ablation zone. With its extremely high acoustic impedance, ice reflects up to 99% of ultrasound signals and produces a characteristic ultrasound appearance within the tissue [54]. This facilitates live visualization of the edge of the iceball at 0 °C, allowing the operator to control the extent of cryoablation using ultrasound guidance. Urethral warming devices protect the urethral mucosa from necrosis during cryotherapy [55, 56]. The use of a warmer is now considered standard of care and reduces the rates of urethral slough, incontinence and urinary retention [57]. Thermosensors are placed immediately prior to the procedure to ensure that a lethal temperature of −20 to −40 °C is achieved in the part of the gland to be ablated, while a safe temperature is maintained in Denonvilliers’ fascia and the urethral sphincter [58]. The ability to deliver lethal ice into the desired ablation zone, use of ultrasound and temperature monitoring, and urethral warming to protect collateral structures makes cryotherapy an excellent modality for focal therapy. In addition, it is suited to focal treatment of anterior zone cancers with its transperineal approach [32].

### High-intensity focused ultrasound

High-intensity focused ultrasound (HIFU) was not widely available in the United States until recently due to regulatory restrictions and much of the experience has been European. Transrectal HIFU represents a truly noninvasive therapeutic modality and is well suited to hemi-ablations and posterior zone focal therapy. However, due to energy dissipation and gradual edema over the intervening prostate tissue, the anterior gland may be more difficult to treat [59–61]. The goal of HIFU is to achieve a target temperature of at least 55 °C for 5 seconds within the ablation zone [62, 63]. MR thermometry is an emerging technique that allows for monitoring to ensure lethal temperatures in the ablation zone and safe temperatures in the urethra and sphincter [64]. However, this would necessitate the procedure to be performed in-bore in the MRI suite and its efficacy remains unproven.

### Transurethral ultrasound ablation

One interesting new development that has arisen due to miniaturization of HIFU probes is transurethral HIFU (transurethral ultrasound ablation (TULSA)) [65]. Via a transurethral approach, HIFU could potentially be much more efficiently applied to the anterior prostate. However, clinical experience with this technology is currently lacking.

### Laser

Laser offers the possibility of truly focal ablation. The ablation zone is guided by the laser fiber and tissue destruction occurs only within a fixed distance from the fiber tip. This allows for accurate and predictable tissue destruction zones that would be theoretically safe within close proximity to vital structures [66]. The disadvantage is that ablation of larger lesions or anatomical zones/regions may be cumbersome with longer procedure times. The laser fiber can be placed transperineally or transrectally via a delivery trocar.

**Table 131.1** Summary of consensus meetings on patient selection 2010–2016.

| | | De la Rosette 2010 [48] | Ahmed 2012 [49] | Donaldson 2015 [50] | Tay 2016 [51] |
|---|---|---|---|---|---|
| Goal | | Eradication of all cancer | Eradication of all cancer | Eradication of clinically significant cancer | Eradication of clinically significant cancer |
| Cancer determination | Overall | TMB | TMB and mpMRI | TMB or systematic + mpMRI | mpMRI + systematic biopsy |
| | mpMRI | Can be recommended at state-of-art centers | Recommended | No clear recommendation | Recommended as far as possible |
| | Biopsy of suspicious lesion | – | To be studied | Recommended | Recommended, MRI-TRUS fusion biopsy |
| | Biopsy of nonsuspicious area | – | TMB | Recommended | Recommended, at least 12-core TRUS biopsy |
| Disease factors | Risk group | Low to moderate risk | – | Intermediate | Intermediate |
| | Maximum grade | – | – | – | 4 + 3 |
| | Maximum size | T2a clinically or T2b radiologically | – | No agreement | Up to 1.5 ml or 3 ml if not crossing midline; up to 20% of prostate volume or 25% if crossing midline |
| | Residual disease permissible | None | None | 3 + 3 up to core length 5 mm | 3 + 3 up to core length 1 mm |
| Patient factors | Age/life expectancy | At least 10 years life expectancy | NA | Not a primary determinant; best suited to life expectancy >10 years and not <5 years | According to major guidelines. No upper or lower limit whereby focal is contraindicated |
| | Sexual function | Effect unknown, counselling recommended | NA | NA | Important, but not the only indication for choosing focal therapy |

TMB, transperineal mapping biopsy; mpMRI, multiparametric magnetic resonance imaging; TRUS, transrectal ultrasound-guided.

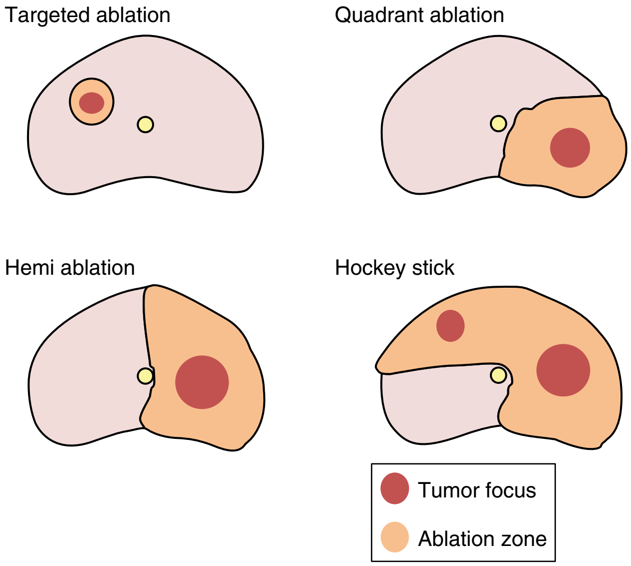

**Figure 131.1** Patterns of ablation.

### Irreversible electroporation

Irreversible electroporation (IRE) is a nonthermal ablative technique that uses short pulses of direct current electricity to produce irreversible pores in the cell membrane, leading to cell death [67]. IRE is lethal only to cells, preserving connective tissue architecture that theoretically could act as scaffolding for new cells to grow. In a 16-patient ablate and resect study, Van den Bos et al. reported that the majority of the men did have fibrinoid necrosis in the unilateral neurovascular bundle and denudation of the prostatic urethra [68]. In this study, the interval between ablation and resection was only one month, and whether the remaining connective tissue does allow regrowth and later functional recovery is unknown.

### Vascular-targeted photodynamic therapy

In vascular-targeted photodynamic (VTP) therapy, low-power near-infrared laser light destroys targeted tissues that have been photosensitized with an intravascular agent preferentially taken up by tumor cells [69]. This results in production of reactive oxygen species in the target zone causing irreversible damage to cell membranes and small arterioles leading to tumor necrosis [70]. Development of the photosensitizer has undergone several iterations with WST9 (TOOKAD®) being used in early trials and the latest being WST11 (TOOKAD Soluble) [71].

### Brachytherapy

Although brachytherapy has been used widely in whole-gland treatment, there has been little published in way of using it for focal therapy apart from simulation studies showing an adequate dose delivery using a focal planning approach [72, 73]. The theoretical benefit with brachytherapy is that the radiation dose decreases rapidly within several millimeters of the radiation source. This allows for a highly conformal approach to radiation delivery. Using seed or low-dose rate (LDR) brachytherapy, urinary toxicity rates seem to be low, and dependent on pretreatment symptoms and urethral dose [74]. On the other hand, high-dose rate (HDR) brachytherapy is associated with a urethral stricture rate as high as 8.2% within the first 2 years of treatment [75]. The majority of these occur at the level of the prostatic apex or bulbous urethra.

### Other modalities

Technical advances in external beam radiation have made it possible to deliver a highly focused dose within the prostate, sparing vital structures [76]. Dosimetric feasibility has been demonstrated in the use of stereotactic body radiotherapy for focal therapy though there has not been any clinical trial [77]. Various nanoparticles used to guide photothermal therapies are still in very early phase [78].

## Choosing the best modality

There is currently no clear benefit of one modality over another in terms of efficacy in tissue destruction. However, the size of the ablation zone and anatomical approach does have implications to successful delivery of ablative energy. For example, the laser tip produces a small ablation zone that is ideal for an image-guided focal ablation of a small lesion, but would take too long if a larger ablation zone is planned (e.g. quadrant or hemi-ablation). Transperineal approaches such as cryotherapy or IRE allow for better access to the anterior gland for anterior focal therapy whereas transrectal HIFU is well-suited to focal destruction of posterior zone cancers [32]. Ultimately, as urologists become conversant with these techniques, an à la carte approach may be adopted, where the modality/delivery combination is adapted to the patient/lesion [59].

## Post focal therapy follow-up

As we move away from whole-gland treatments, traditional markers of therapeutic success are becoming less relevant. After curative radical prostatectomy, PSA is expected to be undetectable and after radiation therapy, a significant rise is needed to define biochemical

recurrence. After focal therapy, however, PSA depends on the amount of residual prostate epithelia that may continue to grow, rendering it less informative. Similarly, clinical examination of the prostate may be affected by posttreatment scarring.

In a 2015 Joint International Consultation on Urological Diseases (ICUD)/Society Internationale de Urologie (SIU) project on image-guided focal therapy, success is defined within the treated or infield area as the eradication of the tumor focus in the short term, and the absence of clinically significant cancer in the intermediate to long term [79]. This consultation also stressed the importance of monitoring the untreated or outfield area for the development of clinically significant cancer, that in the short term, likely represents selection failure, and in the intermediate to long term may represent *de novo* cancer.

A combined strategy of mpMRI and targeted biopsy offer the best available means to monitor the treated and untreated areas. The 2015 ICUD-SIU consultation recommends an mpMRI with mandatory targeted biopsy of 4–6 cores in the treated area at 3–6 months, then mpMRI at 1–2 and 5 years with targeted biopsy as needed. A systematic biopsy is also recommended at 1–2 and 5 years to provide further histological evaluation of the untreated zone for potential outfield recurrence. It should be noted that as yet, there is limited experience with mpMRI in the postfocal treatment arena, and it is unknown how posttreatment changes interact with mpMRI performance. In one whole-gland HIFU series, the sensitivity and specificity of DCE-MRI were reported to be 73–87% and 73–82%, respectively [80]. As radiological experience in postfocal therapy prostates accrues, it will be instructive to learn especially from the treatment failures.

## Contemporary focal therapy series and their outcomes

As mentioned in the beginning of this chapter, a successful focal therapy strategy is the result of a strong multidisciplinary collaboration, with a focus on patient selection, disease determination, accurate delivery of the energy modality, and meticulous follow-up. Focal therapy outcomes must be interpreted in this context. As such, contemporary outcomes of focal therapy series are presented in Table 131.2.

## Conclusions

Focal therapy is an exciting concept that has potential to extend active surveillance and improve quality of life. The cornerstone of success is effective patient selection and careful and meticulous follow-up. However, until long-term outcomes are available, this approach remains under investigation, and urologists should not hesitate to "convert" a patient to whole-gland treatment if the necessity arises.

## Introduction

Focal laser ablation (FLA), or laser interstitial thermal therapy (LITT), refers to localized destruction of prostate tissue by heat from a fiber-coupled infrared laser [1]. Recent advances in the detection of clinically significant prostate cancer (PCa) using magnetic resonance imaging (MRI) now allow for focal treatment of PCa and real-time monitoring of temperature and treatment effects [2, 3]. In contrast to high-intensity focused ultrasound (HIFU), which employs temperatures high enough to cause immediate vaporization, FLA uses temperatures only high enough to cause coagulative necrosis, while avoiding cavitation, vaporization, or carbonization [4]. In contrast to whole-organ treatment, FLA provides localized cancer control with a reduction in treatment-related adverse events frequently seen with surgery or radiation. In recent years, several pilot studies have demonstrated safety and feasibility of FLA using MRI or MRI/ultrasound fusion technology for direct image guidance of the laser fiber [5–8]. However, long-term clinical data regarding oncologic efficacy and patient outcome are currently lacking.

## Principle of focal laser ablation

The use of lasers for local treatment of solid tumors was first proposed in 1983 by Bown [9]. He demonstrated focal tissue necrosis by inserting a 400 μm laser fiber into a metastatic skin lesion [9]. Building on previous work with laser treatment for benign prostatic hyperplasia (BPH), Johnson et al. established feasibility of FLA in a canine model [10]. Prostatectomy specimens demonstrated a confined area of acute coagulative necrosis surrounding each laser fiber pathway [10]. Amin et al. first described the clinical application of FLA for PCa in a patient with local recurrence following radiation therapy [11]. Biopsy of the treatment zone at three months confirmed presence of coagulative necrosis, but revealed cancer cells in the adjacent prostate tissue [11]. Lindner et al. described the first clinical trial of FLA in 12 men with low-risk PCa [5]. All subjects were successfully treated with minimal morbidity following treatment [5]. Further details of this study are discussed later in the chapter.

FLA for PCa involves image guidance to target the region of interest, sufficient thermal tissue effect to destroy the tumor, minimal injury to adjacent tissue, and accurate surveillance of the prostate after treatment [1, 12]. FLA is based on a photothermal effect in prostate tissue [12]. FLA employs temperatures resulting in coagulation necrosis; even brief exposure to temperatures in excess of 45°C causes cell death via coagulation necrosis [13]. Thermal activity results from the absorption of radiant energy by tissue receptive chromophores that rapidly induce coagulation necrosis [12]. Resultant increased temperatures produce protein denaturation and *in vivo* tissue destruction [1]. Optical and thermal properties of the tissue are dictated by its structure, water content, and blood circulation [14]. Prostate tissue is suitable for FLA due to its optical absorption rate without excess vascularity, which allows localized ablation of tumor [14].

## Technology of focal laser ablation

The ultimate goal of FLA systems is to achieve a local tissue temperature rise to 60–85°C to induce coagulation necrosis. Temperature increases occur due to absorption of photons, causing deactivation of target molecules, and

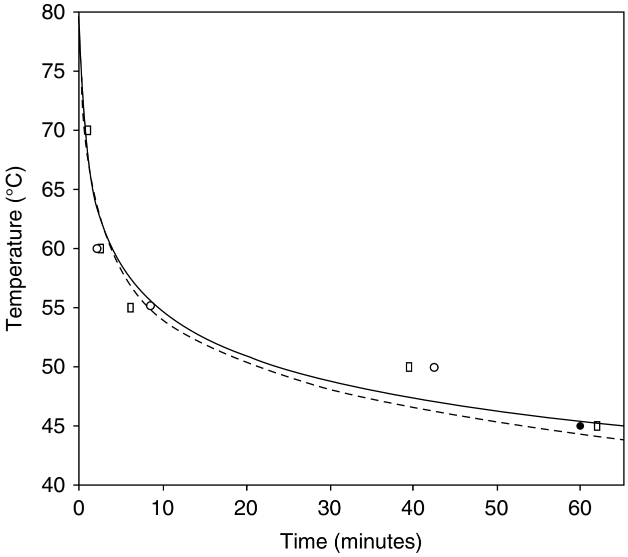

**Figure 132.1** Temperature–time plot for 90% normalized destruction of human benign prostatic hyperplasia (BPH). Open circles represent dye data and open squares histology data. An Arrhenius plot of viability dye and histology results based on 90% normalized destruction of the stromal cells. The *in vivo* data from Larson et al. [18] for the destruction of BPH at 45°C for 1 hour is also plotted for reference (filled circle). *Source:* P Bhowmick et al. In vitro assessment of the efficacy of thermal therapy in human bening prostatic hyperplasia. *Int J Hyperthermia* 2004;20(4): 421–439. Reproduced with permission of Taylor and Francis, Ltd.

ultimately tissue destruction [15]. Energy is delivered using diode lasers that are coupled to laser fibers, thinly spun glass (400–800 µm) with total internal reflection. A diffuser is affixed on the end of the fiber to spread laser energy in a cylindrical, spherical, or conical pattern. Laser parameters that can modify the rate and extent of damage include wavelength, wattage, time, coolant, and tip geometry.

Wavelength choice is important to maximize absorption of laser energy by water and hemoglobin, while maximizing depth of penetration, thus most systems are in the near-infrared range (810 nm, 850 nm, 980 nm) [5, 8, 16]. This tradeoff is also present with the choice of wattage, with lower powers (5–7 W) having slower temperature rises, and higher powers (~30 W) having quick rises, but needing active cooling to prevent fiber destruction. Active cooling can be achieved using a fluid or gas, with existing systems relying on saline or $CO_2$ to actively cool the laser fiber. This active cooling is implemented in existing systems with a dual-lumen, enclosed catheter. Figure 132.1 displays a temperature–time plot of tissue destruction in patients with BPH [17, 18].

FLA is monitored by either MRI or thermal probes, to primarily ensure that sensitive structures (urethra, rectal wall, peri-prostatic nerves) remain below 42°C. MR thermometry measures the proton resonance frequency shift on serial images and yields a relative estimate of temperature in two dimensions, accurate to within a degree [19]. However, this phase shift is sensitive to motion, and artifacts can occur, due to respiration, peristalsis, and at tissue boundaries [20]. The clinical implication of these artifacts is that MR thermometry requires frequent calibration during treatment, and temperature readings outside the prostate may not be valid [6]. Efforts to improve the accuracy and robustness of MR thermometry are ongoing [21]. Conversely, thermal probes provide excellent accuracy but are limited to point measurements [22].

Tissue damage is estimated in real time with the use of the Arrhenius damage model:

$$\Omega(t) = A\int_{0}^{\tau} e^{-\frac{E_a}{RT(t)}}\,dt$$

which gives a rate process for irreversible damage (Ω) as a function of temperature ($T$) [23]. Tissue-specific constants are experimentally derived and vary considerably in the literature. These constants, and the specific point at which irreversible damage occurs, vary with zonal anatomy and prior heating [17]. Contrast-enhanced MRI or ultrasound is then used to confirm the area of damage [5, 8]. Figure 132.2 shows an example of an MRI with Arrhenius-based damage-estimation zone overlay [24].

Future efforts will focus on improved understanding of tissue-specific parameters, influence of cooling sources within the prostate, and large clinical studies to address the variability in prostate tissue response to laser energy.

## Treatment of prostate cancer

### Indications

As with other focal therapies, at this time FLA may be considered for men with clinical stage T2b or less and Gleason score 3 + 4 = 7 or less. Most commonly, FLA is directed at a localized, MR-visible lesion that is suspicious for PCa and confirmed by targeted prostate biopsy cores. Prostate specific antigen (PSA) 20 ng/ml or less and prostate volume 100 ml or less is preferred. Life expectancy in potential FLA candidates should exceed 10 years. Use of FLA following prior treatment for PCa, such as radiation or cryotherapy, has not been reported.

### Temperature monitoring

One of the major advantages of FLA is its compatibility with MRI, allowing for real-time monitoring of temperature changes during FLA treatment [21, 25]. Temperature monitoring, using MR thermometry or thermal probes,

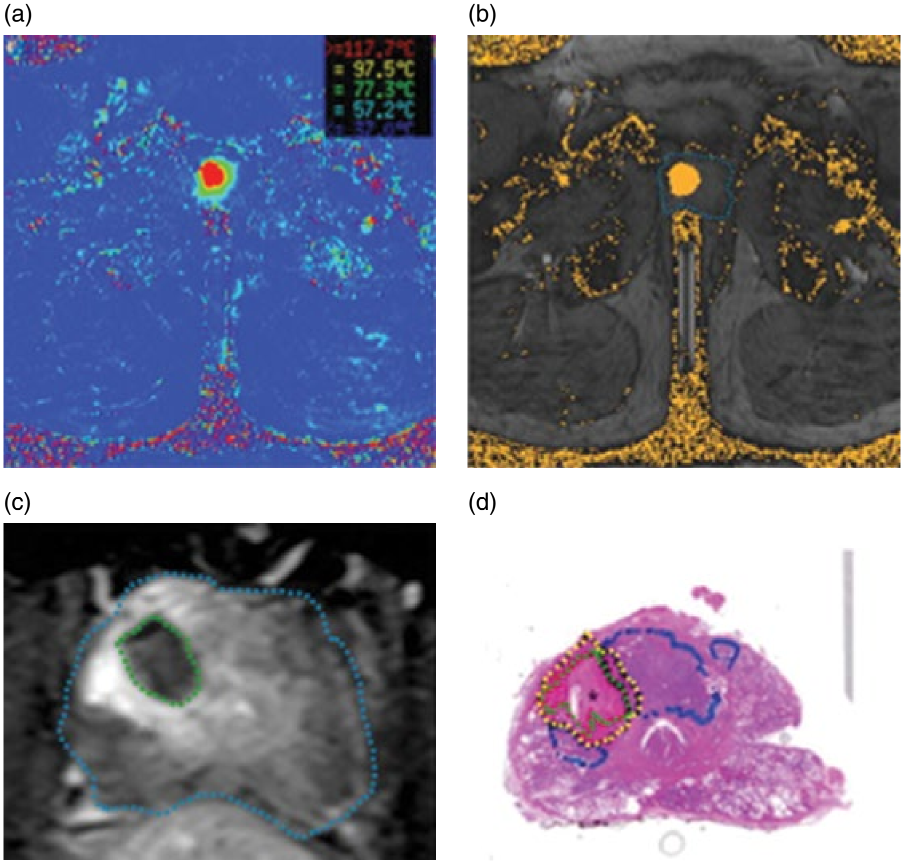

**Figure 132.2** Images of a 67-year-old male with a Gleason score 3 + 4 = 7 in his right transition zone. (a) Real-time MRI–temperature map acquired during focal laser ablation. (b) Anatomical MRI of the prostate (delineated in blue) with the Arrhenius-based damage-estimation zone as orange overlay. (c) Postablation axial T1-weighted contrast-enhanced image. The prostate is delineated in blue and the nonenhancing necrotic tissue in green. (d) Whole-mount H&E stain of the prostate. The necrotic tissue is delineated in green, the perinecrotic tissue in yellow, and vital tumor in blue. *Source:* Bomers JGR, Cornel EB, Fütterer JJ et al. Reproduced with permission of Springer Nature Publishers.

is required for precise determination of the extent of thermal damage in prostate tissues and adjacent structures caused by laser energy [26].

MR thermometry measurements acquired during FLA have previously been used to predict cell death in animal models [27, 28]. Validation of these models has been performed using rigid co-registration between thermometry images and postablation MRI or histology, thus enabling comparison of actual areas of cell death against a simulated temperature map [26–28]. Raz et al. used MR thermometry to monitor thermal tissue damage during FLA in two patients [29]. Thermometry scan was repeated every 6 seconds and laser ablation was ceased when temperatures exceeded 45°C [29].

Another method of measuring intraprostatic temperatures is the use of direct thermal probes placed interstitially. Lindner et al. first used fluoroptic temperature probes for real-time monitoring of intraprostatic temperatures during FLA treatment in 12 patients [5]. Further results from this trial are discussed later in the chapter. In a recent Phase I study, MR-compatible fluoroptic temperature probes were inserted into the prostate using ultrasound guidance, allowing real-time safety monitoring independent of MR thermometry during FLA [6]. In the study, thermal probes were placed at various intraprostatic locations to directly monitor temperatures near the rectal wall, prostatic capsule and urethra [6]. Figure 132.3 illustrates intraprostatic placement of thermal probes during FLA treatment [6].

## MRI-guided focal laser ablation (in-bore)

Several preclinical studies performed in phantom, canine, and cadaveric prostates have demonstrated the feasibility of MRI-guided FLA [30–33]. To date, FLA has generally been performed by an interventional radiologist within an MRI tube (in-bore), allowing for direct image guidance and MRI thermometry for temperature

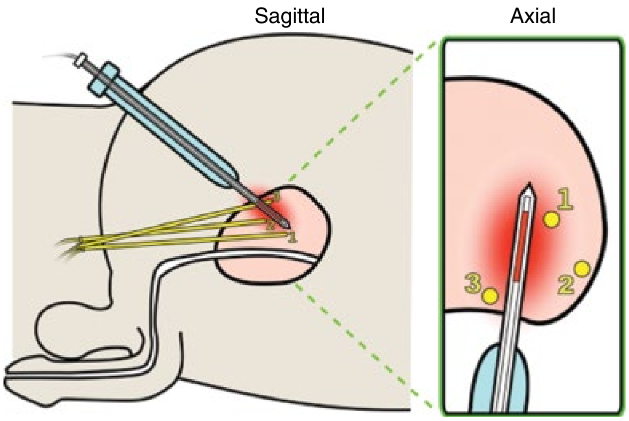

**Figure 132.3** Diagram showing intraprostatic placement of laser fiber (red) and three thermal probes (yellow) during MRI-guided focal laser ablation. Patient is in the prone position within the MRI tube. Thermal probes are used in conjunction with MRI thermometry for independent measurement of temperatures at the margin of treatment zone (1, 2) and near rectal wall (3) as seen on axial inset.

monitoring within the prostate [6]. Raz et al. reported safety and feasibility of in-bore FLA for treatment of low-risk PCa in two patients [29]. No serious adverse events were observed at one month following treatment [29]. Oto et al. demonstrated safety and technical feasibility of MRI-guided FLA in nine men with low-risk PCa [8]. In their study, procedure time ranged from 2.5 to 4 hours and mean laser ablation time was 4.3 minutes with a maximum power of 11.5 W applied during ablation [8]. There were no serious adverse events observed at six-month follow-up [8]. In Table 132.1, a summary of the currently available FLA trials is shown.

In a Phase I trial, Natarajan et al. investigated safety and feasibility of in-bore FLA in eight patients with intermediate-risk PCa [6]. Laser insertion was transrectal and thermal probe insertion was transperineal as in brachytherapy. Both MR thermometry and direct thermal probe recordings were made simultaneously, to assess the accuracy of MR thermometry for monitoring intraprostatic temperatures during treatment [6]. Readings from the probes demonstrated that the thermal effect of FLA was confined to the intended ablation zone with no evidence of heating of adjacent critical structures [6]. There were no serious adverse events observed during six months of follow-up [6]. Total procedure time averaged 292 minutes and actual time in the MRI scanner averaged 223 minutes, intervals similar to those reported in the literature [6, 8].

### Procedure

MRI-guided FLA has been performed to date by an interventional radiologist working within an MRI scanner. Pretreatment high-field 3 T multiparametric MRI, with or without endorectal coil, is performed prior to treatment to establish target lesions, resulting in more accurate laser fiber placement [34]. Targeting of MR-visible regions of interest during FLA treatment is performed using either a transperineal or transrectal approach [34]. In-bore FLA has most often been performed using conscious sedation.

Prior to each procedure, laser fiber locations and desired treatment margins are planned using custom software [6]. Sizeable treatment margins are necessary for complete tumor ablation due to underestimation of prostate tumor volume with current MRI technology [35, 36]. In a recent study comparing preoperative MRI to radical prostatectomy specimens to evaluate MRI accuracy in identifying tumor features, Priester et al. demonstrated that tumor extent may be underestimated by more than 1 cm in most cases [35]. However, future studies are required to define the appropriate treatment margins needed for ablation of the entire tumor.

In-bore FLA is most commonly performed with patients in the prone position on a sliding gantry of the MRI. Once positioned, preliminary images are obtained to identify the region of interest and calculate trajectory angles [34]. An MR-compatible needle guide is then used to insert laser fibers into the prostate. Multiple laser applications, up to 15 W generally, are employed per laser fiber insertion for complete lesion ablation [6]. During treatment, intraprostatic temperatures are continuously monitored using MR thermometry, allowing the detection of any areas that are undertreated or resistant to thermal ablation [34]. FLA is ceased immediately if temperatures exceed monitor thresholds. Irreversible cell death occurs at temperatures greater than 42°C [14]. However, temperatures should not exceed 90°C within the prostate or 40°C near the urethra or rectal wall.

Patients are routinely discharged home within a few hours of treatment with oral analgesics and antibiotics. Prior to discharge, patients should demonstrate spontaneous voiding. Transient urinary retention from prostatic swelling has been an occasional complication. Follow-up clinic visits include PSA, and after 6–12 months, prostate biopsy and MRI. Patients undergoing any form of partial gland ablation are followed as if enrolled in an active surveillance protocol [37].

## MRI/ultrasound fusion-guided focal laser ablation

FLA has generally been performed in an MRI scanner using conscious sedation. With recent advances in MRI/ultrasound fusion technology, localization of tumors using FLA may be performed using MRI/ultrasound fusion guidance. A potential advantage of MRI/ultrasound fusion guidance compared to in-bore FLA is a

**Table 132.1** Treatment and monitoring parameters in studies of focal laser ablation.

| Study | Anesthesia | Real-time imaging | Approach | Laser source | Laser power (W) | Temperature monitoring |
|---|---|---|---|---|---|---|
| Lindner et al. [5] | General | Ultrasound | Transrectal | Indigo diode laser | Unknown | Thermal probes |
| Raz et al. [29] | General | MRI | Transperineal | Visualase diode laser | Unknown | MRI thermometry |
| Oto et al. [8] | Conscious sedation | MRI | Transperineal | Visualase diode laser | 11.5 W | MRI thermometry |
| Lepor et al. [7] | Local | MRI | Transrectal | Visualase diode laser | Unknown | MRI thermometry |
| Natarajan et al. [6] | Conscious sedation | MRI | Transrectal | Visualase diode laser | 11–14 W | MRI thermometry, thermal probes |
| Eggener et al. [44] | Conscious sedation | MRI | Transperineal | Visualase diode laser | 6–15 W | MRI thermometry |

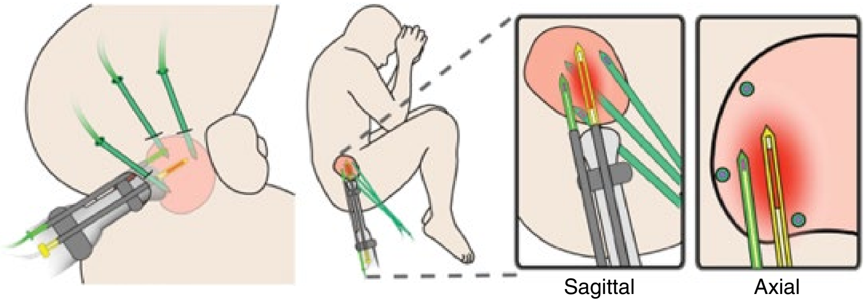

**Figure 132.4** Diagram showing intraprostatic placement of laser fiber (red/yellow) and three thermal probes (green) during MRI/ultrasound fusion-guided focal laser ablation. Laser fiber is inserted transrectally and thermal probes transperineally. Thermal probes provided continuous monitoring of intraprostatic temperature throughout the procedure. Appropriate positioning of the laser fiber within the prostate is constantly verified using real-time ultrasound.

reduction in procedure time by performing the treatment in a clinic setting under local anesthesia without need for real-time MRI visualization. Furthermore, fusion software is able to track biopsy site locations, thus permitting accurate return to the same location within the prostate for FLA treatment and follow-up biopsy [38, 39]. Several fusion devices have been approved by the US Food and Drug Administration (FDA) for commercial use (e.g. Artemis, Eigen, Grass Valley, CA, USA; UroNav, Invivo, Gainesville, FL, USA) [38].

Lindner et al. first demonstrated feasibility of FLA using MRI/ultrasound fusion guidance in 12 patients with low-risk PCa [5]. In their study, an early prototypic fusion device was used to guide the laser fiber to the MRI/ultrasound fused region of interest [5]. FLA was successfully performed in all patients and they observed no perioperative complications and minimal postoperative morbidity [5].

In a recent Phase I trial in 10 men with intermediate-risk PCa (NCT02357121), we investigated the safety and feasibility of FLA using MRI/ultrasound guidance in an outpatient clinic setting under minimal sedation. Total procedure time averaged 95 minutes (range 64–112). All patients were discharged home 1–2 hours following treatment. There were no serious adverse events observed at six months. Figure 132.4 displays an example of MRI/ultrasound fusion-guided FLA.

### Procedure

During MRI/ultrasound fusion-guided FLA treatment, the treating physician images the prostate using ultrasound. While visualizing the prostate on real-time ultrasound, the MRI of that prostate is fused with ultrasound using a fusion device [38]. The fusion results in creation of a patient-specific three-dimensional (3D) prostate model, and on the prostate model, the targeting and ablation of the tumor occurs.

Appropriate positioning of the laser fiber within the prostate is monitored using real-time ultrasound and continuous monitoring of intraprostatic temperatures is performed using thermal probes. The fixed arm of the fusion device provides a fixed platform for insertion and stabilization of the laser fiber during treatment. A motion compensation function in the biopsy tracking software is used to correct discordance from the 3D model due to patient or prostatic movement during treatment. Similar to in-bore FLA, application of laser energy is suspended immediately if temperatures exceed monitor thresholds.

## Effects on prostate tissue

FLA induces a focal area of coagulation necrosis and fibrosis in prostate tissue following treatment [40]. In a study evaluating the effects of FLA on prostate tissue, Lindner et al. demonstrated homogenous coagulation necrosis in the whole-mount prostatectomy specimens of four men with PCa following FLA treatment [41]. Furthermore, these authors observed a localized ablation zone with no evidence of viable cells in treated regions within the prostate [41]. In another study of five men with PCa, Bomers et al. investigated the treatment effects of FLA on prostate tissue prior to radical prostatectomy [24]. Whole-mount prostatectomy specimens revealed a confined area of homogeneous necrosis surrounded by a necrotic area of 1–5 mm thickness with neovascularization and an increased mitotic index [24].

Recent work by our group, in a patient who underwent radical prostatectomy 15 months following FLA, demonstrates the localized treatment effects of FLA [42]. We observed absence of cancer in the treatment zone, but residual cancer in the adjacent prostate tissue [42]. Histology of the treated area revealed a confined, localized area of benign prostatic glands with chronic inflammation, stromal fibrosis, giant cell reaction, and hemosiderin-laden macrophages consistent with thermal effect (Figure 132.5) [42].

## Patient-reported outcomes

Radical prostatectomy and radiation therapy are potentially accompanied by adverse after-effects that impact quality of life [43]. An important reason for selection of focal

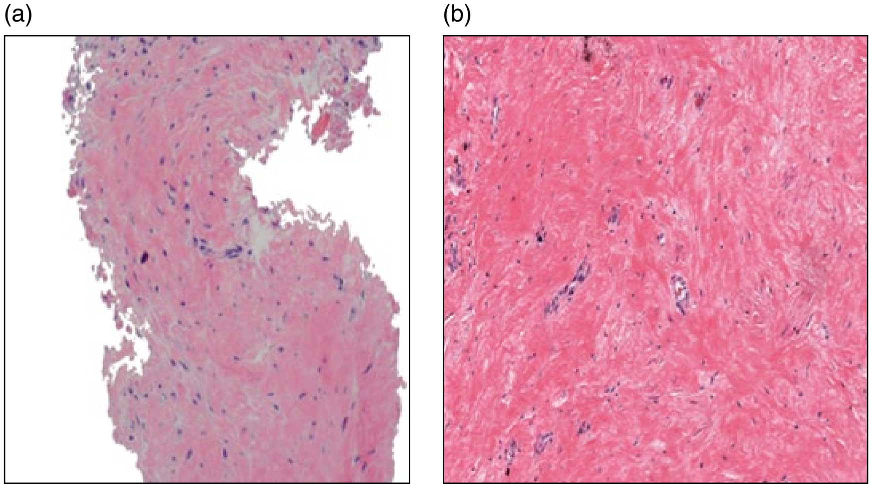

**Figure 132.5** (a) Histology of treatment zone after focal laser ablation treatment showing benign glands with chronic inflammation, stromal fibrosis, giant cell reaction and hemosiderin-laden macrophages consistent with thermal effect. (b) Higher magnification.

therapy is to reduce the chance of treatment-related morbidity. Several FLA trials have employed validated questionnaires to evaluate the effects of FLA on patient quality of life, including urinary and sexual function following treatment [5, 6, 8]. Using the International Prostate Symptom Score (IPSS) and International Index of Erectile Function 5 (IIEF-5) questionnaires, Natarajan et al. observed no significant changes in urinary or sexual function at six months in all men treated with FLA [6]. No urinary incontinence, erectile dysfunction, or change in ejaculation was reported by any patient [6]. Hematuria was the most common adverse event after treatment and resolved without intervention in all cases [6]. Results of FLA studies are shown in Table 132.2.

Lindner et al. reported no significant changes in IIEF-5 or IPSS scores following MRI/ultrasound fusion-guided FLA treatment in 12 men with PCa [5]. In their study, perineal discomfort was the most common adverse event reported (25% of patients) [5]. In a recent Phase II trial investigating in-bore FLA in 27 men with low- to intermediate-risk PCa, Eggener et al. reported hematuria in 4 subjects (15%), perineal ecchymosis in 3 (11%), and acute urinary retention in 2 (8%) after treatment [44]. Similarly, Oto et al. observed no significant changes in urinary of sexual function at six months following FLA treatment [8]. They reported no symptoms indicative of rectal wall toxicity in any patient during follow-up clinic visits [8]. Thus, FLA appears to be relatively safe, especially in comparison to surgery or radiation therapy.

## Effect of focal laser ablation on serum PSA levels

Recent studies demonstrate a varied effect of FLA on PSA after treatment [6–8]. In a study investigating the effects of in-bore FLA treatment for PCa in 25 men, Lepor et al. reported a mean PSA decrease of 2.3 ng/ml between baseline and three months follow-up [7]. Natarajan et al. observed a significant decrease in median PSA from 8 to 3.3 ng/ml six months after FLA treatment [6]. Furthermore, there was a significant decrease in PSA density and increase in percent-free PSA observed [6]. However, Oto et al. observed no significant change in mean PSA from baseline to six months after FLA treatment [8]. The role of serum PSA levels in follow-up of men undergoing FLA is an important topic for further study.

## MRI changes

The extent of tissue necrosis due to FLA is visible on posttreatment MRI. Qualitative and quantitative prostate MRI features before and after FLA treatment have been described [25, 40]. In one recent study, in which whole-mount prostatectomy slices were co-registered with prostate MRI before and after treatment, Litjens et al. observed several changes in MRI features that might function as quantitative tissue biomarkers for treatment response [40]. These authors also found that residual disease and ablated tissue could not be completely differentiated by postablation MRI alone [40].

In a study of four men with PCa, Lindner et al. observed a correlation between volumes of thermal damage that were visible on MRI and those determined via staining of whole-mount radical prostatectomy specimens after FLA treatment [41]. Oto et al. demonstrated a hypovascular defect on dynamic contrast-enhanced MRI immediately after FLA treatment in eight patients [8]. In another study of eight men with PCa, Natarajan et al. observed a well-defined, underperfused region on DCE MRI in each patient immediately after FLA. There were no consistent changes in T2- or diffusion-weighted

**Table 132.2** Clinical results of focal laser ablation studies.

imaging, and median prostate volume decreased [6]. Figure 132.6 displays the MRI of a patient before and after FLA treatment [6].

## Oncologic efficacy

Eggener et al. observed no cancer in 26 of 27 men (96%) three months after in-bore FLA [44]. At 12 months, three men (11%) had cancer in the treatment zone and eight (30%) had cancer identified outside the treatment zone on repeat biopsy [44]. Most residual cancer identified was clinically insignificant [44].

At six-month targeted biopsy, Natarajan et al. identified no residual cancer in the ablation zone in five of eight men (63%), and no cancer outside the treatment zone in two of eight men (25%) after in-bore FLA [6]. Lindner et al. demonstrated that 50% of patients had no evidence of cancer on biopsy six months after FLA treatment [5]. In their study, 67% of patients had no cancer identified in the treated area [5]. Lepor et al. reported that 26 of 28 sites biopsied three months after FLA treatment had no evidence of residual PCa [7].

## Focal laser ablation after radical prostatectomy

Local recurrence of PCa after whole-organ treatment with radical prostatectomy occurs in 25–30% of cases [45]. Experience using FLA to treat post-prostatectomy local recurrence is limited to a single reported case [46]. In that report, Woodrum et al. used MRI guidance to detect PCa recurrence, then inserted a laser fiber via a trans-perineal approach [46]. MRI effectively allowed identification of the recurrent tumor and ablation with the laser fiber [46]. DCE MRI after the procedure had no definitive abnormal enhancement [46]. No posttreatment biopsy was performed [46].

## Conclusion

Laser ablation is a promising treatment alternative for localized, organ-confined prostate cancer, further enhanced by its ease of integration with high-resolution 3 T multiparametric MRI. Several recent studies have demonstrated safety and technical feasibility of FLA using direct MRI guidance or MRI/ultrasound fusion guidance. However, long-term clinical data regarding its effect on patient quality of life and oncologic efficacy are sparse. Further research is necessary to establish FLA as a viable alternative to whole-organ treatment. Future clinical studies will aid in defining treatment margins and identifying appropriate candidates for FLA treatment.

## Introduction

Prostate cancer remains the most common cancer in men; for 2018, an estimated 164 690 cases will be diagnosed (19% of all cancers), with 29 430 deaths (9% of all cancers in men) [1]. Only 10% of prostate cancer diagnoses in the prostate specific antigen (PSA) testing era are high-risk prostate cancers, which justifies approaches that focus treatment on the prostate itself and minimize impact on quality of life.

According to the National Comprehensive Cancer Network (NCCN) guidelines [2], reasonable approaches to the management of non-metastatic prostate cancer include surgical approaches and radiation approaches (external beam radiation therapy (EBRT), brachytherapy, or a combination of both), potentially supplemented by androgen-deprivation therapy. EBRT using relatively few sessions of highly focused, high-dose-per-session radiation therapy (hypofractionation, generally referred to as stereotactic body radiation therapy (SBRT) or stereotactic ablative radiosurgery (SABR)) [3, 4] is becoming more widely accepted as well, but is practiced primarily in experienced centers. Brachytherapy is an approach that allows permanent (low dose rate, or LDR) or temporary (high dose rate, or HDR) delivery of radioactive isotopes within the prostate, which deliver localized therapeutic dose though decay of radioactive isotopes and emission of radiation. Other treatment modalities, including cryotherapy [5] and radiofrequency ablation (RFA) [6] appear to be effective in select cases, but are not yet considered standard of care.

In this chapter we review the history, techniques, and outcomes of brachytherapy approaches in the management of prostate cancer.

## History of prostate brachytherapy

Prostate brachytherapy is one of the oldest radiation therapy techniques, first described by Pasteu and Degrais in 1913 [7] and brought into regular use by Young, the pioneer of the radical perineal prostatectomy [8, 9]. Interstitial techniques were originally performed with digital guidance alone using transperineal radium needles as reported by Barringer, a urologist practicing at the New York Memorial Hospital in his 1924 publication, detailing cases starting as early as 1915 [10]. This needle-based approach was later supplanted by less expensive gold-encapsulated seed treatments [11]. Due to poor visualization of the target, these techniques yielded poor oncologic outcomes, and were not widely adopted. Subsequently, an open surgical retropubic approach was utilized by Whitmore and colleagues at Memorial Sloan Kettering Cancer Center starting in 1970, which also included a bilateral pelvic lymphadenectomy [12, 13]. Local control was still poor with this technique (only 44% at 10 years in node-negative patients), which was felt to be due to suboptimal seed distribution within the prostate gland. In addition, the procedure required a laparotomy, and soon lost favor compared to modern prostatectomy and EBRT approaches.

Image-guided (ultrasound-based) transperineal prostate brachytherapy was introduced by Holm et al. in 1983 [14] and subsequent developments in multiplanar transrectal ultrasound (TRUS) allowed for safe and effective transperineal placement of radioactive sources [15–17]. Subsequently, multiple techniques have been developed incorporating imaging both before (preplanning) and during (intraoperative) LDR brachytherapy implantation procedures to deliver optimal therapy, and robust long-term

Companion website: www.wiley.com/go/smith/textbookofendourology

outcomes and toxicity data have been generated through prospective trials and large institutional experiences. In addition, new techniques for temporary HDR brachytherapy have been developed, after Yoshioka et al. [18] reported the favorable results of HDR brachytherapy as monotherapy for various risk groups of localized prostate cancer in 2000. Guidelines for LDR and HDR prostate brachytherapy have been established by the American Brachytherapy Society (ABS) [19, 20] and its role in the management of prostate cancer is further delineated in the NCCN guidelines [2]. Technical standards for prostate brachytherapy are also well established, with formal roles for the physician and medical physicist and reporting guidelines set by the American Association of Physicists in Medicine (AAPM) [21]. Dosimetric parameters and reporting for permanent prostate brachytherapy are also carefully defined in the AAPM Task Group reports 43 and 137 [22, 23].

## Patient selection for prostate brachytherapy

In terms of radiation-based treatment approaches in the management of prostate cancer, brachytherapy is appealing in that it is the most conformal treatment available for the prostate, focusing the vast majority of radiation exposure on the target organ while limiting dose to the rest of the body more than any other radiation technique, including advanced charged-particle therapy. In addition, the treatment can be delivered in a single session with certain approaches. Prostate brachytherapy is generally an outpatient procedure and the patient may resume 100% of physical activity within 24 hours after implantation and treatment delivery is complete.

Appropriate patient selection is crucial in the application of prostate brachytherapy. Guidelines have been set forth by the American Urological Association (AUA) [24] and the ABS [19, 20]. According to the ABS, there are several absolute contraindications to TRUS-guided permanent prostate brachytherapy, including inability to tolerate spinal or general anesthesia; the presence of distant metastases (identified clinically or on metabolic or cross-sectional imaging); large defects from a prior transurethral resection of the prostate (TURP) that would preclude effective seed placement; life expectancy of less than 10 years; or the presence of the ataxia telangiectasia (AT) mutation, which would predispose to excessive toxicity from radiation.

Other considerations include a high International Prostate Symptom Score (IPSS) [25] of >20 (although it was noted that most prospective studies have used a cutoff score of 15 or 18), history of prior radiation therapy to the pelvis, large median lobes (e.g. Figure 133.1), prostate volume >60 ml at the time of implant, or inflammatory bowel disease [26–29]. For patients with enlarged prostates that would present a technical challenge to implant (due to pubic arch interference, for example, as shown in Figure 133.2), cytoreduction with androgen-deprivation

therapy (ADT) is an option, with average reduction in prostate volume of approximately 30% after 3–4 months [30, 31]. Both bicalutamide and luteinizing hormone-releasing hormone analogs (LHRHa) can provide effective ADT-based cytoreduction; in a study by Petit et al. [32] median cytoreduction was 26% for bicalutamide and 32% for LHRHa methods, with greater sexual function-related toxicity in the LHRHa group.

Prostate brachytherapy is ideal for the management of prostate cancer confined to the prostate gland, similar to radical prostatectomy. The risk of extraprostatic disease should be considered when selecting treatment. ABS recommendations based on NCCN risk group suggests that prostate brachytherapy alone without supplemental EBRT or ADT is appropriate for low-risk prostate cancer, as well as intermediate-risk prostate cancer; of note, for those patients with high- to intermediate-risk disease, supplemental EBRT and/or ADT should be considered [33]. Brachytherapy alone (monotherapy) is not recommend for patients with high-risk prostate cancer, and supplemental EBRT and ADT are favored [20]. The recommendations are mirrored in NCCN guidelines for the management of prostate cancer [2].

According to the ABS guidelines, there is no absolute lower or upper age limit for prostate brachytherapy, and studies have not shown a significant difference in outcome for patients treated at a younger age (<60 years) compared to patients treated over 60 years of age [34]. A common issue raised when deciding between radiation and surgery-based approaches in the management of prostate cancer is the risk of a secondary cancer from exposure to radiation therapy, particularly bladder and rectal cancers [35–37]. However, when examining the risk of secondary cancers by treatment modality, it has been noted that brachytherapy does not carry the same association with secondary cancers as EBRT, likely due to its highly conformal nature with minimal exposure to normal tissue [36, 38–40]. The possibility of an increased risk of secondary cancers, especially if brachytherapy is combined with EBRT, should still be discussed with each patient.

Brachytherapy (both LDR and HDR) may be used as salvage therapy in the setting of a localized prostate recurrence [2].

## Technical issues in prostate brachytherapy

### Approach, visualization, and access for prostate brachytherapy

Brachytherapy implantation is generally performed according to the method described by Holm et al. [14, 15] via a transperineal approach with real-time ultrasound visualization of the prostate. The TRUS probe is generally mounted on a stepper unit attached to a stabilizer arm, which supports the probe and template grid and facilitates a calibrated caudal/cephalad motion (Figure 133.3). Accurate placement of the needles is achieved with this

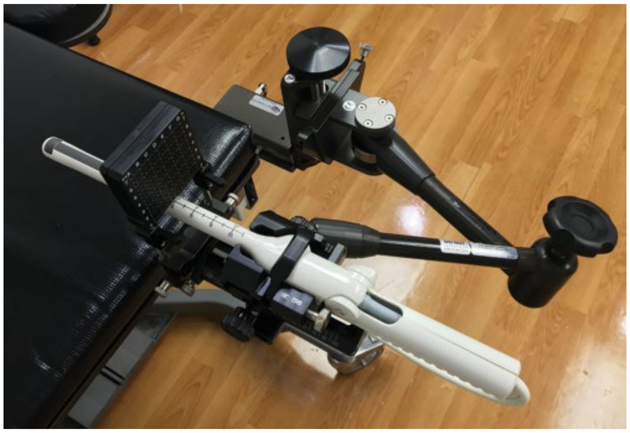

**Figure 133.3** Transrectal ultrasound probe mounted on stepper/stabilizer unit for brachytherapy procedures.

technique, which allows real-time adjustment of implanted needles relative to the target organ (Figure 133.4). Once needle placement is confirmed, the radioactive isotopes may be delivered through them into the substance of the prostate gland, either permanently (LDR approaches using $^{125}$I, $^{103}$Pd, $^{131}$Cs, see Figure 133.5) or temporarily (HDR approaches generally using $^{192}$Ir afterloader) (Figure 133.6).

## Low dose rate permanent prostate brachytherapy

### Source selection for low dose rate prostate brachytherapy

Perhaps the most common isotope used for permanent prostate brachytherapy is iodine-125 ($^{125}$I) first introduced in 1965, which is often sold in the form of silver iodide deposited on a silver rod, sealed in a titanium shell.

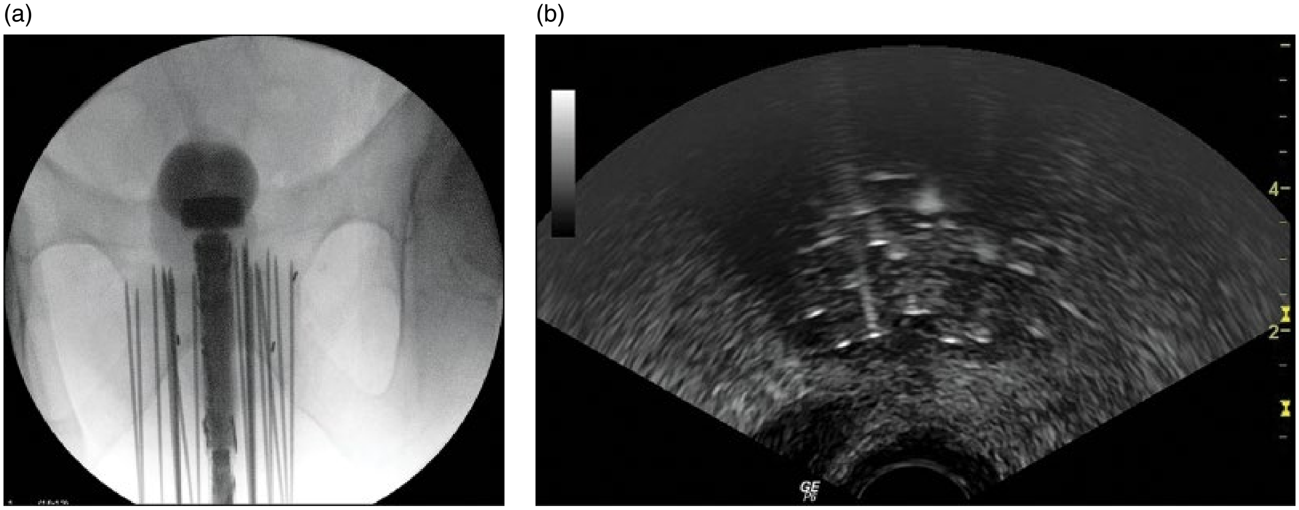

**Figure 133.4** Implanted needles in the prostate gland visualized on (a) fluoroscopic and (b) ultrasound imaging.

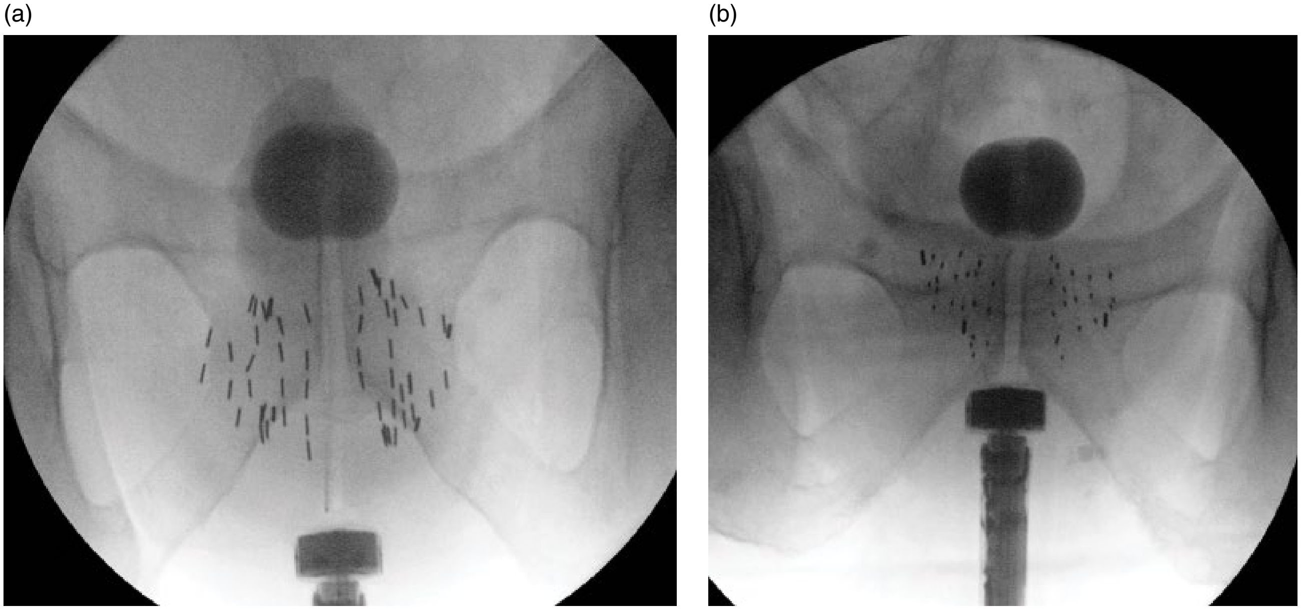

**Figure 133.5** Postprocedure fluoroscopic images of implanted seeds: (a) $^{125}$I implant; (b) $^{103}$Pd implant.

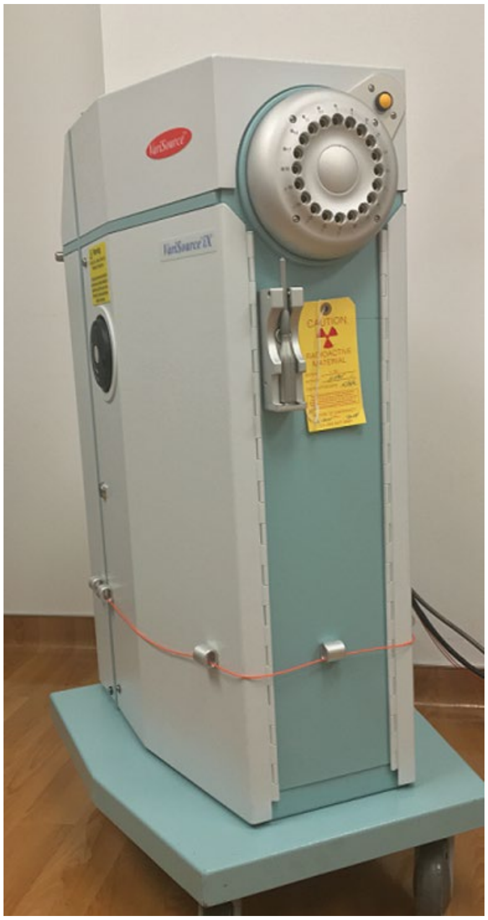

Figure 133.6 Typical afterloader used in high dose rate brachytherapy procedures (Varian Varisource IX afterloader, Varian Inc.).

$^{125}$I emits photons from electron capture decay (half-life ($T_{½}$) of 59.4 days) with energies ranging from 27.4 to 35.5 keV, as well as lower energies resulting from interaction with the seed materials (average energy 27.4 keV). Palladium-103 ($^{103}$Pd) was introduced in 1986. $^{103}$Pd decays in the same manner as $^{125}$I but with a shorter half-life ($T_{½}$ of 17 days), emitting photons with energies of 20.1 and 23 keV. Cesium-131 ($^{131}$Cs) was introduced in 2004 for permanent prostate brachytherapy. $^{131}$Cs has the shortest half-life of the standard commercially available radionuclides ($T_{½}$ of 9.7 days) with photon energies ranging from 29.5 to 34.4 keV (average energy 30.4 keV), similar to $^{125}$I. This allows dose delivery over a shorter overall time interval, thus limiting the period during which patients must follow radiation safety precautions [19, 21].

It has been hypothesized that a more rapid rate of dose delivery would result in a greater activity against high-grade tumors due to their faster doubling time [41], but this has not been borne out in multiple studies. In a prospective randomized trial comparing $^{125}$I versus $^{103}$Pd implants by Wallner et al. [42] there was no difference in 3-year actuarial biochemical control rates for patients with low-risk prostate cancer. In a more recent study by Kollmeier et al. that included patients with low-, intermediate-, and high-risk localized prostate cancer [43], no differences were noted in long-term genitourinary or gastrointestinal toxicity or 5-year biochemical relapse-free survival for patients treated with $^{125}$I versus $^{103}$Pd implants. The "strength" of the source, measured by its activity, may play a role; in a randomized trial by Narayana et al. [44] higher strength $^{125}$I implants were found to have improved dosimetric coverage at a lower overall seed cost, with shorter operating room times; the study was not designed to assess long-term toxicity or clinical outcome.

### Pre- and intraoperative planning and treatment delivery for LDR brachytherapy

As optimal dosimetry requires placement of seeds in a distribution that provides optimal coverage of the prostate gland while reducing dose to critical nearby structures (urethra, bladder/bladder neck, and rectum), careful planning is required to determine appropriate seed placement. This can be done in advance of the actual operative procedure (preplanning) or on the same day of the procedure (intraoperative planning) [45]. In general, patients undergo a gentle bowel preparation prior to the day of their planning procedure with Fleet's enemas or laxatives; patients undergoing both planning and treatment on the same day following an intraoperative protocol require a more thorough bowel preparation such as HalfLytely. Percutaneous brachytherapy treatment planning is performed by placing the patient in extended lithotomy position, and introducing the TRUS probe into the rectum (Figure 133.3). The prostate and surrounding organ anatomy is surveyed to identify possible issues during treatment, such as pubic arch interference (see, for example, Figure 133.2), which would interfere with anterior needle placement; this can also be assessed in part by prior cross-sectional (CT or MRI) imaging [46]. The "volume study" used to generate the plan is constructed by acquiring consecutive axial ultrasound images at 5 mm intervals from the base of the prostate to the apex, with a superimposed and calibrated template on each image. Longitudinal images are also acquired to ensure that no axial slices were missed and to verify the base to apex length measurement [21] (Figure 133.7).

The preplanning approach generally calls for linked or stranded seeds to be placed based on an implant plan generated from the TRUS-based "volume study" acquired prior to the actual procedure date, although a preplan can also be used to generate a manual/individually placed seed distribution. One advantage of techniques using

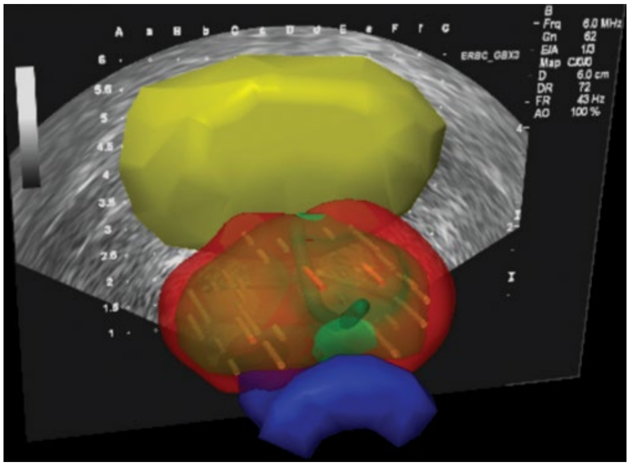

**Figure 133.7** Three-dimensional reconstruction of prostate volume study. Bladder depicted in yellow, prostate in light green, urethra in dark green, and rectum in blue. The prostate is encompassed by a dose cloud in red generated by the implanted seeds.

stranded seeds is that the seeds are much less likely to migrate from their planned positions within and around the prostate; this has been evaluated in a prospective trial by Reed et al. [47] in which they compared two groups of patients; one group used seeds held in a #1 Vicryl strand, and the other used loose seeds. They did not identify a significant dosimetric difference between the two approaches, although there was significantly more seed loss in the loose seed cohort. It is unclear if this seed loss is clinically significant. Saibishkumar et al. also studied the clinical impact of the stranded versus loose seed approach [48] and found that the use of stranded seeds increased unfavorable dosimetric parameters for the rectum and urethra, and resulted in a trend towards increased acute toxicity rate.

Intraoperative planning, in comparison, is performed at the time of the implant, and accounts for patient anatomy in the anesthetized state; this process can be done both prior to needle placement [49] or after the needles are placed [45]. While many variations exist for this form of treatment, plans performed prior to needle placement generally utilize preloaded seeds and spacers or stranded seeds, whereas plans generated after needle placement utilize an applicator (such as the Mick Applicator shown in Figure 133.8, Mick Radio-Nuclear Instruments Inc., now an Eckert & Zigler BEBIG Company, Mount Vernon, NY, USA) that allows individual, manual seed placement according to the plan under direct real-time ultrasound visualization. Both techniques have been evaluated against preplanned seed placement. Shah et al. compared preplanned brachytherapy against intraoperative, pre-needle plans and found that the intraoperative plans provided superior dosimetric and biochemical control outcomes [49]. Zelefsky et al. compared preplanned brachytherapy against intraoperative 3D optimized plans following needle placement and found that the intraoperative technique improved both target coverage as well as reducing dose to the urethra and rectal wall [45]. Investigators have also incorporated a “dynamic-adaptive” planning approach that takes into account the contribution of each manually placed seed as the procedure is performed, allowing for intraoperative modification of treatment to reduce the risk of a suboptimal plan [50].

### LDR prostate brachytherapy implant quality assessment

Clinical outcomes following brachytherapy administration have been shown to be strongly related to the quality of the implant. This assessment of quality is performed following implant administration in the setting of LDR brachytherapy with 3D imaging of the prostate

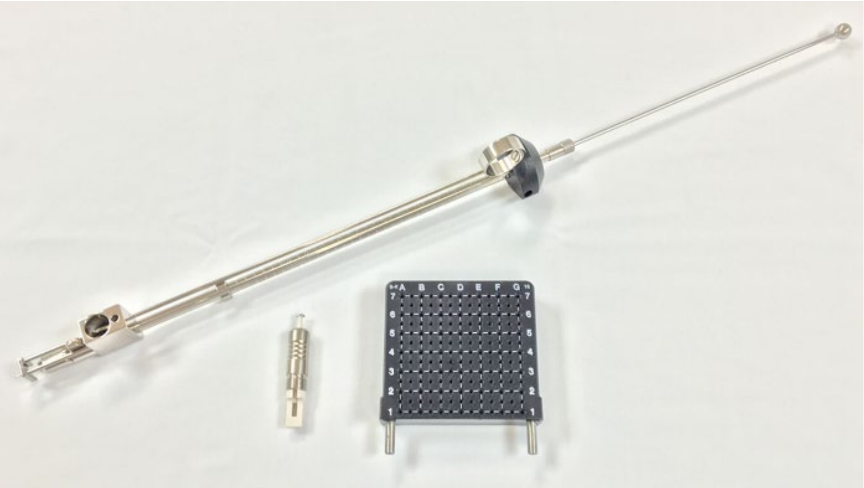

**Figure 133.8** Mick applicator, seed cartridges, and needle placement template grid.

performed at a set time point after treatment; generally 30 days of $^{125}$I implants, although earlier assessments may also be performed (especially for $^{103}$Pd and $^{131}$Cs, with their more rapid decay). Multicenter pooled studies have been performed to evaluate the prognostic impact of post-implant dosimetry on ultimate outcome. In a report by Stone et al. [51], data from 3928 permanent brachytherapy implants at six institutions was analyzed, and doses of ≥140 Gy were correlated with improved biochemical control. The dose to the prostate is assessed in terms of the minimum dose delivered to 90% of the prostate volume ($D_{90}$) as measured on CT imaging [52]. Another multi-institutional analysis of patients with T1–T2 prostate cancer treated with permanent seed implantation corroborated this conclusion, showing that $D_{90} < 130$ Gy was associated with increased risk of biochemical recurrence [53]. Other target dosimetric parameters often assessed include the prostate volume receiving 100% of the prescribed dose ($V_{100}$) and the prostate volume receiving 150% of the prescribed dose ($V_{150}$) [22, 23].

## High dose rate temporary prostate brachytherapy

Although permanent interstitial brachytherapy with radioactive seeds has been a standard treatment for localized prostate cancer for decades, HDR brachytherapy, using a temporary source introduced using a remote afterloader, is a much more recent advance (see Figure 133.5). HDR brachytherapy is defined as the delivery of radiation at a dose rate of >12 Gy per hour [20]. The technique for HDR temporary prostate brachytherapy is similar to that of LDR brachytherapy performed with intraoperative planning; needle implantation is performed with an anesthetized patient in extended lithotomy position under TRUS guidance. Treatment needles can be placed directly, or "pathfinder" needles may be placed and then replaced with flexible plastic guide catheters. The treatment needles or guide catheters are held in place with a template locked and sutured to the perineum. In some institutions, they may be held in place by a rigid foam or dental sealant. Flexible cystoscopy is generally performed to ensure that the treatment needles/catheters are not inserted into the urethra or through the bladder wall. Imaging is then acquired for treatment planning (ultrasound, CT, or MRI), and a computer-optimized treatment plan is generated (Figure 133.9). The remote afterloader is then attached to the needles or catheters and treatment is delivered; the implant can then be removed or left in place if additional fractions are planned [54].

HDR brachytherapy may offer many advantages over LDR brachytherapy, including increased likelihood of tumor control due to the high biological effectiveness of high-dose fractions (assuming a low α/β ratio for prostate cancer), data suggesting reduced rates of acute and late toxicity relative to permanent seed implantation [55], improved conformality of dose to the prostate (potentially superior to SABR/SBRT [56]), and no permanent radiation sources within the prostate (reducing radiation safety concerns from dose delivery to the patient's family and associates) [57].

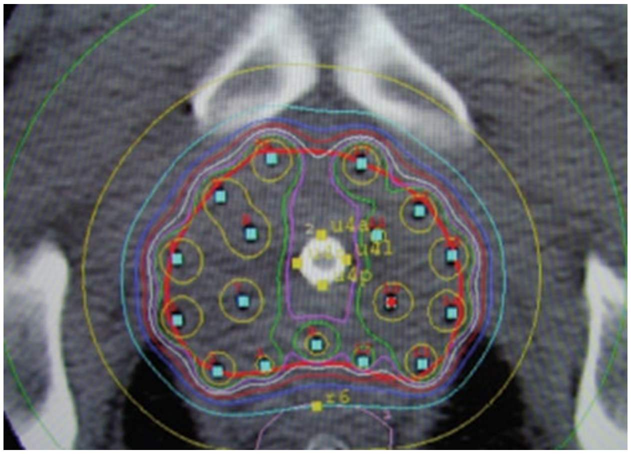

**Figure 133.9** High dose rate prostate implant plan; 17 needles placed. Foley catheter in place in center.

Both the ABS [20] and the American College of Radiology (ACR) have provided guidelines (appropriateness criteria) for the use of HDR brachytherapy in the management of prostate cancer [58]. In terms of patient selection, the ABS recommendations are similar to those for LDR brachytherapy, although an additional absolute contraindication was added for preexisting rectal fistula.

## Salvage brachytherapy

Brachytherapy is a reasonable option as salvage treatment for locally recurrent prostate cancer initially treated with EBRT. Because brachytherapy delivers highly conformal therapy, bladder, and in particular urethral and rectal doses can be stringently minimized while high doses can be given to tumor-bearing prostate tissue, making brachytherapy an excellent treatment option for patients who have failed EBRT. Both LDR and HDR techniques have been reported for the salvage of local radiation failures.

Burri et al. [59] reported the results of salvage LDR brachytherapy in 37 patients with a median follow-up of 86 months. A median dose of 140 Gy was administered. The 5-year and 10-year biochemical relapse-free survival was found to be 65% and 54%, respectively.

Grade 3–4 toxicity was noted in 11% of patients, including one patient who developed a rectal fistula. A Phase II study of salvage LDR brachytherapy has completed accrual. HDR brachytherapy has also been used successfully in the salvage setting. In a Phase II trial from Memorial Sloan Kettering Cancer Center, 42 patients who had local recurrence underwent whole-gland HDR brachytherapy, receiving 800 cGy × 4 in one insertion over two days. The actuarial biochemical relapse-free survival probability was found to be 70% at 5 years. Rectal toxicity was minor, and patients demonstrated worse urinary symptoms after salvage HDR, with 20% probability of developing a grade 2 event [60].

## Combination therapy (use of both brachytherapy and EBRT)

The limited penetration of therapeutic dose beyond the prostate capsule by low-energy photon brachytherapy sources may be limiting in patients with risk for significant extraprostatic disease extension. Conversely, for these high-risk patients, EBRT alone has been associated with a significant failure rate, which is reduced by the addition of long-term ADT [61–63] and radiotherapy dose escalation [64–66]. Even with contemporary dose-escalated EBRT, a meta-analysis suggests that plateau of benefit has not yet been reached [67], and the requirement for long-term ADT persists, as demonstrated by the DART 01/05 trial [68]. Supplementation of brachytherapy with EBRT, or "combination therapy," is argued to retain the unique intraprostatic dose escalation of brachytherapy while improving extraprostatic coverage. The dose of supplemental EBRT, sequencing of treatment, and choice of LDR or HDR is largely set by institutional preferences in the absence of strong comparative data.

For EBRT dose, while one randomized trial from a high-volume group found no difference between 44 Gy EBRT + 90 Gy $^{103}$Pd boost versus 20 Gy EBRT + 115 Gy $^{103}$Pd boost [69], few high-grade or locally advanced patients were included, and the excellent biochemical control of 93% at 10 years is a testament both to a likely more favorable risk population than is the primary beneficiary of combination therapy and that group's expertise. In general, many still use 40–50 Gy of supplemental EBRT dose.

With regard to sequencing of the implant, those who use brachytherapy first before EBRT, such as the authors of this review, cite the potential benefits of (i) minimizing pre-implant urinary symptoms/swelling to reduce risk of acute urinary obstruction and (ii) allowing supplemental EBRT to address deficiencies in the implant dosimetry. For LDR implants in this sequence, $^{103}$Pd is favored for its shorter half-life in order to minimize overlap in dose delivery with EBRT, initiated four weeks after the implant. Other institutions, such as UCSF, and contemporary NRG/Radiation Therapy Oncology Group (RTOG) protocols (i.e. RTOG 0924) prescribe brachytherapy boosts about four weeks after completion of EBRT. A Phase II randomized feasibility study of HDR brachytherapy before or after EBRT for combination therapy in high-risk prostate cancer patients is ongoing in the United Kingdom [70], in an attempt to address this question.

The choice of LDR or HDR for the brachytherapy similarly remains subject to institutional preference, as well as tradeoffs in their relative strengths as discussed elsewhere in this review. The ACS-ABR 2015 practice parameter on permanent LDR implant notes typical $^{103}$Pd dose of 80–110 Gy and $^{125}$I dose of 100–110 Gy when given in conjunction with EBRT, with the recommendation to consider the resultant biologically effective dose (BED) as delineated by investigators at Mt. Sinai [71, 72]. Constraints on organs at risk are largely institution dependent but should consider urethra and rectal dose most prominently and according to an institutional standard. The literature on HDR EBRT regimens is even more varied, with institutional preference again dominating choice but perhaps an overall trend towards fewer fractions to take advantage of the theorized low $\alpha/\beta$ ratio rationale for hypofractionation, as reviewed by Morton and Hoskin [73] and noted in the 2012 ABS practice parameter statement on HDR brachytherapy [20]. Common approaches include 7 Gy × 3, 10.5 Gy × 2, 15 Gy × 1, and constraints vary strongly according to regimen published.

## Prostate brachytherapy dose selection and organ-at-risk constraints

When developing a prostate brachytherapy treatment plan, multiple considerations are involved, both in terms of appropriate coverage of the target organ (the prostate), and how best to protect proximal structures (organs at risk, or OARs) such as the urethra, bladder, and rectum. Guidelines have been provided by the ABS based on review of the available literature, clinical trials, and the experience of designated committees for both LDR and HDR brachytherapy [19, 20]. The NCCN also provides some guidance with respect to appropriate dose prescriptions and utilization [2].

In terms of LDR prostate brachytherapy, ABS recommends prescribed doses for LDR monotherapy of 140–160 Gy for $^{125}$I and 110–125 Gy for $^{103}$Pd implants. When administering combination therapy with EBRT (41.4–50.4 Gy given in 1.8 Gy per fraction), these doses are reduced to 108–110 Gy for $^{125}$I and 90–100 Gy for $^{103}$Pd implants [19]. According to NCCN guidelines, the recommended prescribed doses for LDR monotherapy are 145 Gy for $^{125}$I and 125 Gy for $^{103}$Pd implants. When administering combination therapy with EBRT (generally 40–50 Gy given at 1.8–2 Gy per fraction), these doses are reduced to 110 Gy for $^{125}$I and 90–100 Gy for $^{103}$Pd implants [2]. According to ABS recommendations, OAR constraints are provided for the urethra and rectum; for the urethra, the goal is to keep the percent volume of the urethra receiving 150% of the prescription dose ($UV_{150}$) to <5% (effectively a point maximum given the small volume of the urethra), and the percent volume of the urethra receiving 125% of the prescription dose ($UV_{125}$) to <30%; for the rectum, the goal is to keep the volume of rectal wall receiving 100% of the prescription dose ($RV_{100}$) to <1 cm$^3$ on the preplan and <1 cm$^3$ on post-implant dosimetry.

For HDR prostate brachytherapy, given the flexibility of dose administration, a wide range of dose and fractionation regimens are possible, with monotherapy treatment delivered in 1–6 fractions (from single-fraction doses as high as 24 Gy in a single fraction to six fraction treatments of 6.5–7.25 Gy per fraction), and boost treatments (with external beam doses of 41.4–50.4 Gy given in 1.8 Gy per fraction) ranging from 15 Gy in one fraction to four fractions of 6 Gy per fraction. According to NCCN guidelines, HDR brachytherapy can be performed as monotherapy or in combination with EBRT; for monotherapy, two fractions of 13.5 Gy each is proposed, and when combined with EBRT (again, generally 40–50 Gy given at 1.8–2 Gy per fraction), two fractions of 9.5–11.5 Gy per fraction, three fractions of 5.5–7.5 Gy per fraction, or four fractions of 4–6 Gy per fraction are appropriate [2]. According to ABS recommendations, OAR constraints for urethra, rectum, and bladder are deferred to those used at experienced centers; the maximum urethral dose is generally kept to less than 110–130% of the prescription dose, and the dose to 1–2 cm$^3$ of the bladder and rectum are kept to less than 70–80% of the prescription dose [20].

Although these constraints are useful in planning appropriate treatment for prostate cancer with brachytherapy, continuous evaluation of the impact of dose to organ substructures is ongoing, as a dose measurement to the urethra as a whole may not be as relevant as the dose to an organ subunit. Due to the preponderance of genitourinary toxicities in prostate brachytherapy, areas of particular interest are the bladder neck and the bladder trigone; a study by Hathout et al. [74] investigated the impact of dose to the bladder neck, defined as the region 5 mm around the catheter-defined urethra between the catheter balloon and the prostatic urethra, and identified that patients receiving >50% of the prescription dose to 2 cm$^3$ of the bladder neck were at higher risk of developing ≥ grade 2 acute and late genitourinary toxicity.

## Results of prostate brachytherapy treatment

### LDR prostate brachytherapy outcomes

Prostate brachytherapy has mature longitudinal outcome data and has been shown to be a highly effective therapy. Attempts to compare prostate brachytherapy as monotherapy to radical prostatectomy in a prospective randomized trial was attempted in the Alliance for Clinical Trials in Oncology (ACOSOG Z0070) (Surgical Prostatectomy Versus Interstitial Radiation Intervention Trial (SPIRIT)) trial, but it was closed early due to non-accrual, having enrolled only 56 of a planned 1980 patients [75, 76]. Comparison studies using biochemical (PSA) surrogates suggest that prostate brachytherapy is at least equivalent to radical prostatectomy and possibly superior to EBRT. There is no clear role at this time for the addition of ADT to LDR prostate brachytherapy when used as monotherapy for the treatment of low- or intermediate-risk prostate cancer.

Potters et al. [77] reported on their experience with prostate brachytherapy in 1449 patients with Gleason 6–7 prostate cancer, showing an overall 12-year biochemical freedom from recurrence (BFR) using the ASTRO-Kattan definition of 78%; for low-risk patients, 12-year BFR was 89%. Grimm et al. [78] reported a PSA progression-free survival at 10 years of 87% for low-risk patients (PSA <10, Gleason score ≤6, cT1–T2b). Multi-institutional outcomes were reported by Zelefsky et al. [53] with pooled data from 11 institutions for 2693 patients with non-metastatic T1–T2 prostate cancer (including patients with Gleason scores up to 10, no PSA limit) treated with brachytherapy monotherapy. The 8-year biochemical relapse-free survival according to the ASTRO definition was 82%, 79%, and 48%, respectively, for low-, intermediate-, and high-risk patients. Notably, they found that for all patients with quality implants (where the dose to at least 90% of the prostate, or $D_{90}$, was ≥130 Gy), the 8-year biochemical relapse-free survival was 93%, compared to 76% for those with poor-quality implants. For patients ≤60 years of age with clinically localized low- or intermediate-risk prostate cancer, Kollmeier et al. [79] reported 8-year biochemical relapse-free survival outcomes of 97% for low-risk patients and 94% for intermediate-risk patients; of those potent prior to treatment, erectile function was preserved in >50% of patients and the majority (66%) did not require erectile dysfunction medication.

In a prospective Phase II trial conducted by Lawton et al. (RTOG Study 98-05) [80] designed in part to test the portability of ultrasound-guided prostate brachytherapy to the community setting (rather than specialized centers only), 101 patients from 27 institutions were treated with $^{125}$I permanent interstitial brachytherapy. Patients had T1b–T2a disease, and most (88%) had Gleason 6(3 + 3) disease with a median PSA of 5.9 ng/ml. With a median follow-up of 8.1 years, there were no prostate cancer-specific deaths, and the cumulative incidence of biochemical failure was only 8%. Incidence of grade 3 toxicity was 3.2% (all genitourinary), and there were no higher grade toxicities. This compared favorably to surgical series such as the Scandinavian Prostate Cancer Group Study Number 4 (SPCG-4) trial reported by Bill-Axelson et al. [81], where ADT intervention was performed in over 20% of patients at 8 years, and in a large cohort of 1055 patients with cT1–3a NxM0 cancer treated with radical prostatectomy reported by Kattan et al. [82] biochemical failure at 8 years was approximately 30%.

## HDR prostate brachytherapy outcomes

HDR prostate brachytherapy does not have as long a track record as LDR prostate brachytherapy, but has been heavily investigated with prospective trials. Yoshioka et al. [18] first reported the favorable results of HDR brachytherapy as monotherapy for patients with localized prostate cancer in 2000 (including all T-stages). With a median follow-up of 5.4 years, the 5-year biochemical relapse-free rate was 83%.

Subsequently, five prospective Phase I/II trials of HDR monotherapy with promising results have been published [55, 57, 83–85]. Martinez et al. [83] treated 41 patients with Gleason 6–7 disease with PSA ≤10 and T-stage ≤ cT2a, with 38 Gy in four fractions, which was well tolerated. Corner et al. [84] reported on 100 patients with locally advanced prostate cancer (T-stage ≤ T3b, PSA <40, N0/M0), who received escalating doses from 34 Gy in four fractions to 31.5 Gy in three fractions; no biochemical recurrences were observed, albeit with median follow-up of no more than 30 months. Ghilezan et al. [86] reported on 94 patients with T-stage ≤ cT2b, Gleason 6–7 prostate cancer with PSA ≤12, who received 24–27 Gy in two fractions. Treatment was well tolerated with no > grade 2 genitourinary or gastrointestinal toxicities. Zamboglou et al. [87] reported on 718 patients with localized prostate cancer (low-, intermediate-, and high-risk patients were eligible) treated with 34.5–38 Gy in 3–4 fractions. Eight-year biochemical control for the entire cohort was 90%; at 5 years, biochemical control was 95%, 93%, and 93%, respectively, for low-, intermediate-, and high-risk patients. Hauswald et al. [88] reported long-term outcomes for 448 patients with low- and intermediate-risk prostate cancer treated with 42–43.5 Gy in six fractions. At 10 years, biochemical progression-free survival was 98.9% and 95.2% for low- and intermediate-risk patients, respectively.

More recently, Prada et al. [89] reported the first single-fraction HDR monotherapy data, in which 40 patients with favorable clinically localized prostate cancer were treated with a single fraction of 19 Gy. To reduce the risk of rectal toxicity, a transperineal injection of hyaluronic acid into perirectal fat to increase the distance between the prostate and rectum was performed prior to treatment [90]. The 32-month actuarial biochemical control was 100% and 88%, respectively, for low- and intermediate-risk groups with no ≥ grade 2 gastrointestinal or genitourinary toxicity. HDR prostate brachytherapy has proven to be a highly effective and well-tolerated treatment modality across the prostate cancer spectrum, and increased utilization is expected. There is no clear role at this time for the addition of ADT to HDR prostate brachytherapy when used as monotherapy for the treatment of low- or intermediate-risk prostate cancer.

## Combination brachytherapy and EBRT outcomes and patient selection

Patient selection for combination therapy follows the same technical considerations for monotherapy; however, what level of disease risk requires combination therapy remains debated. Although there is consensus on adding supplemental EBRT to brachytherapy for high-risk disease, it is less clear when combination therapy is beneficial in intermediate-risk patients, compared to either EBRT alone or brachytherapy alone. The randomized Phase III trial RTOG 0232 in intermediate-risk patients comparing combination EBRT/brachytherapy versus brachytherapy alone is closed and its pending report upon maturation of follow-up will offer critical data. In the interim, given the good prognosis of "favorable" intermediate-risk patients [33], the benefit of combination therapy in intermediate-risk patients is likely most appreciable in those with multiple risk features. In this context, while an early study by Blasko et al. [91] found no benefit to combination therapy versus brachytherapy alone (5-year biochemical relapse 15% vs. 16%), it is quite possible that its retrospective design contains residual confounders from initial treatment selection that obscure true differences in a subgroup of patients.

In a similar vein, two older studies randomized intermediate/high-risk patients to EBRT with or without brachytherapy and found reduced biochemical relapse, but these used definitive EBRT doses (55–66 Gy) now considered subtherapeutic. Since that time, select primarily single-institution retrospective studies have demonstrated improved relapse-free survival or positive biopsy reduction with combination EBRT and brachytherapy [92, 93], even translating into reduction of distant metastasis risk in a series from Memorial Sloan Kettering Cancer Center of intermediate-risk patients [94] and in a multi-institution comparison of Gleason 9–10 patients undergoing combination therapy versus EBRT versus prostatectomy [95]. Perhaps the most convincing argument in favor of the benefit of combination brachytherapy and EBRT for treatment of prostate cancer has come from the abstract presentation of the ASCENDE-RT Phase III trial, which randomized 276 high-risk (69%) and 122 intermediate-risk (31%) patients to EBRT alone (78 Gy total) versus EBRT (46 Gy) and LDR brachytherapy boost (115 Gy $^{125}$I) following a year of ADT [96]. With median follow-up of 6.5 years, there was a significant reduction in biochemical relapse (7 years 71% vs. 86%), at the cost of increased acute and late urinary toxicities. As it remains the case that no prospective randomized study in prostate cancer has yet demonstrated a metastasis risk reduction or survival benefit to dose escalation of radiotherapy, many are eagerly awaiting the long-term data of this study required for evaluation of such clinical endpoints.

## Toxicity and quality of life

Due to the close proximity of critical structures such as the urethra, bladder, and rectum, some toxicity from brachytherapy is unavoidable. Although high-grade toxicity is low, even grade 2 toxicity may significantly affect patient quality of life, and informed consent of the risks and benefits of treatment must be obtained from the patient. A prospective quality-of-life (QOL) study for patients undergoing radical prostatectomy, brachytherapy, or EBRT for prostate cancer was reported by Sanda et al. in 2008 [97]. Patients receiving brachytherapy had better performance in the sexual domain than surgery or EBRT, but were noted to have worse performance in urinary domains (irritation, obstruction) than other treatment modalities. A prospective cohort study of 704 patients with low- and intermediate-risk prostate cancer treated with radical prostatectomy, EBRT, or brachytherapy was reported by Ferrer et al. in 2013 [98]. In their study they also showed that prostate brachytherapy had increased irritative/obstructive complaints relative to EBRT and surgery, but had the least impact on sexual function and bowel complaints. The relative benefit of brachytherapy compared to other treatment modalities in terms or retained sexual function continues to be borne out in recent studies [99].

Keyes et al. [100] reported on a group of 2011 patients with NCCN low- and low- to intermediate-risk prostate cancer treated with $^{125}$I LDR brachytherapy, with a minimum follow-up of 25 months (median 54.5 months), who had been followed with prospective assessment of treatment quality and genitourinary toxicity. Late RTOG grade 0, 1, 2, 3, and 4 toxicity was seen in 70%, 21%, 6.4%, 2.3%, and 0.08% of patients, respectively. QOL assessments were also performed on the RTOG 98-05 study reported by Feigenberg et al. [101] demonstrating an overall very good heath-related QOL following prostate brachytherapy, with transient increases in urinary incontinence to 14% at six months, decreasing to 1% at 1 year, and decrease in ability to achieve erection from 73% at baseline to 57% at 1 year.

## Comparative effectiveness and value

In 2008, the Institute for Clinical and Economic Review (ICER) released their final appraisal of prostate brachytherapy versus intensity-modulated EBRT or proton beam therapy [102]. Based on an analysis of 166 studies, they found that prostate brachytherapy carried the lowest lifetime cost (US$29 575 for brachytherapy, US$41 591 for intensity-modulated EBRT, and US$72 789 for proton beam therapy), although there was relatively little difference in quality-adjusted life years (QALYs) (13.9 for brachytherapy, 13.81 for intensity-modulated EBRT, and 13.7 for proton beam therapy).

This benefit may be maintained against nonradiation treatment modalities as well. Hayes et al. [103] conducted a cost-effectiveness analysis for observation versus initial treatment in patients with low-risk prostate cancer using Medicare scales; treatments included brachytherapy, intensity-modulated EBRT, and radical prostatectomy. Although they found observation to be more cost-effective than initial treatment, for patients who did proceed to treatment, prostate brachytherapy was the most effective and least expensive initial therapy. The base-case average lifetime costs for patients aged 65 were US$24 520 for watchful waiting, US$35 374 for prostate brachytherapy, US$38 180 for radical prostatectomy, US$39 894 for active surveillance, and US$48 699 for intensity-modulated EBRT. A French multicenter study was conducted by Buron et al., comparing prostate brachytherapy to prostatectomy [104]; this study used the validated EORTC Quality of Life Questionnaire (QLQ) as well as comparative cost analysis. They found that the two treatments were similar in cost at 2 years (8019 euros for brachytherapy vs. 8715 euros for prostatectomy), and that QOL measures were acutely worse in prostatectomy, but slightly better long term. A nationwide charge comparison in the United States of the costs associated with the treatment of early-stage prostate cancer has shown that brachytherapy administered as monotherapy is associated with the lowest costs compared with radical prostatectomy alone, EBRT alone, and any combination of treatment modalities [105, 106]. In particular, significant cost benefits have been noted in comparison to the use of intensity-modulated EBRT [107].

## Conclusions

In this chapter, we have discussed the history, technical aspects, outcomes, and cost-effectiveness of LDR and HDR brachytherapy approaches in the management of prostate cancer. Prostate brachytherapy has been shown to be an effective treatment for localized prostate cancer, with high-quality long-term outcomes data. Given the relatively favorable prognosis of men with prostate cancer and the wide range of treatment modalities available to treat them, careful patient selection and frank discussion of the relative risks and benefits of available therapy is critical. For patients who choose radiation-based management of their prostate cancer and meet eligibility criteria, brachytherapy should be the primary treatment modality offered given the significant cost-effectiveness advantage over external beam approaches.

# Image-guided External Beam Radiotherapy

*Brett Cox, Lucille Lee, & Louis Potters*

*Department of Radiation Medicine, Northwell Health, New Hyde Park, NY, USA*

## Introduction

External beam radiotherapy (EBRT) has been revolutionized by incorporating modern imaging technologies to precisely deliver radiation. In combination with advanced radiation planning techniques such as intensity-modulated radiation therapy (IMRT) and arc therapy, image-guided radiation therapy (IGRT) allows for high radiation doses to be delivered to the tumor while sparing adjacent normal tissues. Recent advances in the delivery of radiation therapy include harnessing the advances in diagnostic imaging modalities and incorporating them into the planning and delivery of treatment. Examples include computed tomography (CT), magnetic resonance imaging (MRI), and positron emission tomography (PET). In addition, modern computer technology has made it easier to incorporate an increasing number of customized beams and tumor-tracking technologies during radiotherapy delivery, which allows the radiation dose to be further concentrated in the area of interest. The advent of these high-quality imaging techniques coupled with the use of computerized treatment delivery systems have enhanced the accuracy of delivering radiation dose to a target to within millimeters and are the hallmarks of IMRT, stereotactic body radiotherapy (SBRT), and stereotactic radiosurgery (SRS).

Decades ago, traditional radiation treatments used wide margins to accommodate potential movement or other spatial uncertainties during a treatment course. Doses often had to be limited due to the exposure of radiosensitive nearby structures. With more precise image-guided treatments, the dose to a target structure can be increased while reducing the dose to a neighboring critical structure. Certain areas, such as the brain, are particularly amenable to these types of treatments because movement is minimal or can be easily controlled. Many other parts of the body are prone to movement with loss of subcentimeter accuracy with, for example, casual breathing. This respiratory motion is increasingly being accounted for in modern radiotherapy treatments. In addition, tumors can change, either shrinking or actually growing during the treatment course. These movements and changes result in reduced accuracy and either underdosing the target or overdosing nearby critical structures. Treatments can be replanned multiple times during a treatment course for a target that changes in size; this is a promising new technology referred to as image adaptive radiation therapy (IART). For targets that maintain the same size but are more prone to movement, various methods may be used to compensate for that movement.

IGRT is particularly useful for treatment of prostate cancer, where the target size is relatively stable but is prone to movement. IGRT allows for dose escalation, which has been shown to improve the outcome of radiation for localized prostate cancer. Despite higher doses, the increased accuracy allows for tighter margins to be used, resulting in low morbidity. This chapter details the use of IGRT for the treatment of prostate cancer.

## Prostate cancer

### Epidemiology

Prostate cancer is the most common cancer in males. In 2015, 220 800 cases were expected in the United States, with 27 540 expected deaths. Approximately 90% of cases are diagnosed in the locoregional stages, for which the 5-year relative survival approaches 100%. The recent decreases in annual incidence reflects, in part, the decreased rates of detection resulting from reduction in

the widespread use of prostate specific antigen (PSA) screening that peaked in the 1980s and 1990s. Mortality has been declining since 1990 [1].

## Screening

The role of PSA screening in asymptomatic men remains controversial. In 2012 the US Preventative Services Task Force issued a “D” recommendation for PSA screening [2], but several professional organizations, including the American Urological Association (AUA), continue to recommend PSA screening in selected populations [3]. These conflicting recommendations are due to differences in interpretation of the available evidence regarding the risks and benefits of PSA screening. Published randomized trials comparing the mortality outcomes of a screened group versus a nonscreened group demonstrated conflicting results [4, 5], but both studies suggested a high rate of overdetection and treatment. The AUA currently recommends patients between 55 and 69 years old be offered biennial screening in the context of shared decision-making. They recommended no screening for patients under 40 or over 69 years and concluded that there was not sufficient evidence to recommend screening in men aged 40–54 years. The core recommendation in the new AUA guideline is that men aged 55–69 be offered PSA-based screening for prostate cancer through a shared decision-making process that accounts for their values and preferences. The guideline states than men under 40 or over 69 years of age should not be screened, with the caveat that some men in their 70s with excellent life expectancy may benefit. The most significant reversal from the 2009 best practice statement is that the guideline does not recommend routine screening for men aged 40–54. Any consideration of PSA screening should be in the context of an informed discussion of the risks and benefits of prostate cancer screening prior to biopsy and allowing full consideration of the option of active surveillance instead of treatment for certain patients found to have prostate cancer [3].

## Risk stratification

Once the diagnosis of prostate cancer is made, an appropriate staging workup ensues in order to provide additional prognostic information for risk stratification, which may assist in management decisions. The National Comprehensive Cancer Network (NCCN) Version 3.2016 provides recurrence risk stratification among patients with clinically localized disease based on PSA level, Gleason score, clinical stage, and biopsy specifics (Table 134.1). The American Joint Committee on Cancer (AJCC) incorporates PSA and Gleason score into a stage/prognostic group system (Table 134.2), while the TNM

**Table 134.1** Prostate cancer recurrence risk according to the National Comprehensive Cancer Network (NCCN) Practice Guideline in Oncology 3.2016.

| | |
|---|---|
| Very low | T1c |
| | Gleason < 6 |
| | PSA < 10 ng/ml |
| | <3 positive cores |
| | PSA density < 0.15 ng/ml/g |

| | T Any | N1 | M0 | PSA Any | Gleason Any |
| | T Any | N Any | M1 | PSA Any | Gleason Any |

system for clinical and pathologic staging remains the same. A CT or pelvic MRI is recommended for patients with T3 and T4 disease and for patients with a nomogram indicated probability of lymph node involvement >10%. A bone scan is recommended for the following patients: T1 disease with PSA >20 ng/ml, T2 disease with a PSA >10 ng/ml, Gleason score 8 or higher, T3 disease, T4 disease, and patient with symptoms consistent with bony metastases.

## External beam radiation therapy for prostate cancer

### Patient selection

Patients with disease localized to the prostate without evidence of lymph node or distant metastasis may be candidates for definitive EBRT. There are relatively few general contraindications to the use of radiation therapy for treatment of definitive disease. These include prior treatment with pelvic radiation therapy and presence of active autoimmune disease, particularly scleroderma and lupus. Inflammatory bowel disease may be considered a relative contraindication for patients undergoing pelvic node irradiation, since treatment may be poorly tolerated [6, 7], but may be safe for patients undergoing treatment to the prostate alone [8]. Patients with low- or very low-risk group disease can be treated with either EBRT or brachytherapy. Patients with intermediate-risk disease can be treated with EBRT ± androgen-deprivation therapy (ADT) and ± brachytherapy or brachytherapy alone. Patients with high- and very high-risk group disease are treated with EBRT ± ADT ± docetaxel chemotherapy and ± brachytherapy.

#### Selecting patients for brachytherapy

When deciding whether or not to use brachytherapy, either alone or in combination with EBRT, it is useful to consider pretreatment urologic symptoms and prostate size. Acute urologic symptoms may also be more severe with brachytherapy, which makes it less ideal for patients with significant symptoms of benign prostatic hypertrophy (BPH) and those with large glands, the general cutoff being 50–60 ml. Urinary symptoms are commonly rated using the AUA International Prostate Symptom Score (IPSS) (Table 134.3), which is the same at the BPH Symptom Score but with a quality-of-life (QOL) question added. The American Brachytherapy Society suggests that patients with IPSS >15–17 are not ideal candidates for brachytherapy [9]. A history of transurethral resection of the prostate (TURP) is a relative

**Table 134.3** International Prostate Symptom Score (IPSS).

| | Not at all | Less than 1 time in 5 | Less than half the time | About half the time | More than half the time | Almost always | |
|---|---|---|---|---|---|---|---|
| Over the past month, how often have you had a sensation of not emptying your bladder completely after you finished urinating? | 0 | 1 | 2 | 4 | 4 | 5 | |
| Over the past month, how often have you had to urinate again < 2 h after you finished urinating? | 0 | 1 | 2 | 4 | 4 | 5 | |
| Over the past month, how often have you found you stopped and started again several times when you urinated? | 0 | 1 | 2 | 4 | 4 | 5 | |
| Over the past month, how often have you had a weak stream? | 0 | 1 | 2 | 4 | 4 | 5 | |
| Over the past month, how often have you had to push or strain to begin urination? | 0 | 1 | 2 | 4 | 4 | 5 | |
| | **None** | **1 time** | **2 times** | **3 times** | **4 times** | **5 or more times** | |
| Over the past month, how many times did you most typically get up to urinate from the time you went to bed at night until the time you got up in the morning? | 0 | 1 | 2 | 4 | 4 | 5 | |
| Total symptom score ________________ | | | | | | | |
| | **Delighted** | | | | | | **Terrible** |
| If you were to spend the rest of your life with your urinary condition just the way it is now, how would you feel about that? | 0 | 1 | 2 | 3 | 4 | 5 | 6 |

contraindication to brachytherapy because of the increased risk of urethral toxicity, including incontinence, and poor dosimetry. Other factors that contribute to higher acute toxicity include a greater number of needles used to do the implant and the use of hormonal therapy [10].

### Combination external beam radiation therapy and brachytherapy

There are no high-quality published data to support either using EBRT alone or combination EBRT and brachytherapy in the treatment of intermediate- to high-risk prostate cancer. However, at the time of press, a large prospective, randomized Canadian trial, the ASCENDE-RT trial, has reported in abstract form that combination therapy with EBRT and brachytherapy offers superior biochemical control when compared to EBRT alone in patients with intermediate- and high-risk group prostate cancer when radiotherapy is given with androgen deprivation. In theory, the higher incidence of extracapsular extension and seminal vesicle invasion in intermediate- to high-risk patients is more adequately covered by EBRT than brachytherapy, which is the rationale for avoiding brachytherapy alone in these patients. On the other hand, certain intermediate-risk patients are likely to be candidates for brachytherapy alone. In a retrospective review of 668 brachytherapy patients, there was no statistically significant difference in the 8-year actuarial biochemical relapse-free survival (BRFS) between low- and intermediate-risk patients, 98.4% and 98.2%, respectively [11]. These data suggest that most intermediate-risk patients have a low risk of micrometastatic disease in the pelvis. Even though the risk of extracapsular disease is higher in these patients, these areas may be adequately covered by an implant, since most extracapsular disease is located within 5 mm of the prostate capsule [12]. In another series of combination therapy, where 63.4% of the intermediate-risk patients had 50% or more positive biopsy needle cores, there was an 80% 15-year BRFS [13]. These data suggest excellent long-term control with the combined approach. However, despite high control rates, the additional use of EBRT may be detrimental in terms of higher rates of morbidity. Therefore, additional pathologic factors, such as number or percentage of positive cores, may be helpful to determine whether or not a combination treatment should be used.

### Postprostatectomy external beam radiotherapy

Adjuvant or salvage EBRT is used in the postprostatectomy setting. Adjuvant radiation is given based on pathologic findings at surgery. In general, the indications for postprostatectomy adjuvant radiation therapy include: positive margins, seminal vesicle invasion, extracapsular extension, and detectable PSA. The European Association for Research and Treatment of Cancer (EORTC) 22911 prospective Phase III trial randomizing postprostatectomy patients with capsular penetration, positive margins, and/or seminal vesicle invasion to immediate radiation therapy of 60 Gy versus observation, showed an improvement in biochemical disease-free survival (BDFS) and disease progression, but no overall survival advantage. The 5-year progression-free survival was 74% for patients undergoing radiation therapy versus 52% undergoing observation. The 5-year rate of grade 3 urinary toxicity was 2.6% in the observation arm and 4.2% in the treatment arm ($P = 0.0726$). Similar findings were reported in a multi-institutional randomized clinical trial comparing adjuvant radiation therapy of 60–64 Gy to observation with a median follow-up of 10.5 years. The metastasis-free survival was 64.5% in the treated group versus 56.9% in the observation group ($P = 0.06$) [14]. More provocatively, the SWOG 8794 trial, with similar design, has demonstrated improvements in biochemical control, local control, distant metastases-free survival, and overall survival when immediate adjuvant radiotherapy is delivered for patients with pathologic T3 disease or positive margins [14].

Salvage radiation therapy is given when the patients experience a postsurgery biochemical recurrence. Salvage radiation has been shown to improve biochemical progression and early salvage radiation at low PSA levels is associated with improved BPFS and rates of distant metastases [15]. There are no trials comparing adjuvant and early salvage radiation therapy.

## Results

### Definition of biochemical failure

Results are generally reported by risk group and using BRFS since significant overall survival data may require decades to obtain. The definition of biochemical failure was changed in 2006. The previous definition was the American Society for Therapeutic Radiology and Oncology (ASTRO) definition for biochemical failure, which required three consecutive rises in PSA above the nadir. Because of problems including backdating and the phenomenon of a temporary benign PSA bounce [16], the Phoenix definition of PSA nadir plus 2 ng/ml has been adopted, which offers a better balance between sensitivity and sensitivity [17]. With either definition, the dependence of outcome on dose and risk group is clear.

### Dose escalation

Numerous high-quality prospective Phase III randomized trials demonstrate the importance of dose escalation in prostate cancer. These trials demonstrate that when radiation doses are increased from 64–70 Gy to 74–80 Gy, there is a 10–20% improvement in rates of biochemical control [18–22]. A meta-analysis of randomized controlled trials suggested that high dose was beneficial for all risk groups compared to conventional dose treatments [23]. As these trials mature, more tangible clinical improvements are being noted in addition to biochemical control. The MD Anderson dose escalation trial has demonstrated with dose escalation improves rates of distant metastases and prostate cancer deaths in patients with high-risk disease and PSA >10. These improvements in outcome were offset by an increase in the 10-year incidence of Radiation Therapy Oncology Group (RTOG) grade 3 gastrointestinal toxicity was significantly higher with the 78 Gy dose (26% vs. 13%), partially attributed to outdated 3D planning techniques. Significantly higher grade 2 or greater gastrointestinal toxicity was also seen, but there was no significant difference in genitourinary toxicity [23]. Furthermore, a meta-regression analysis predicted close to 100% biochemical control for doses around 90 Gy, especially for the low-risk group.

### Combination therapy

Randomized data demonstrating the benefit of combination therapy in patients with intermediate- and high-risk disease is maturing and has been presented in abstract form (ASCENDE-RT). Numerous retrospective studies also support combination therapy. Long-term BRFS rates for 223 patients with clinical stage T1–T3 prostate cancer treated from 1987 to 1993 with $^{125}$I or $^{103}$Pd brachytherapy after 45 Gy neoadjuvant EBRT without ADT were reported using different risk models. The results for a subset of intermediate-risk patients were described above. Overall, the 15-year BRFS for the entire treatment group was 74%. By risk group, the 15-year BRFSs were: low risk 85.8%, intermediate risk 80.3%, and high risk 67.8% ($P = 0.002$) [13]. Zelefsky et al. have reported that combination-based treatment approaches improve PSA relapse survival as compared with contemporary dose-escalated radiation alone [24].

### Whole-pelvis radiation therapy for high-risk disease

Whole-pelvis radiation therapy is used for high-risk disease to treat microscopic involvement of the pelvic lymph nodes. The dose to the pelvis ranges from 4500 to 5040 cGy in standard fractionation. A higher dose to the prostate can be given as an external beam cone-down or with brachytherapy. RTOG 94-13 was a four-arm study randomizing patients who are at greater than 15% risk of pelvic node metastasis to whole-pelvis or prostate-only radiation therapy and neoadjuvant or adjuvant ADT. At last analysis, it was not clear that there is an advantage to whole-pelvis radiation over prostate-only radiation [25]. Although a whole-pelvic field has been standard for many trials treating high-risk prostate cancer, two of which are described below, further research will be needed to answer the question definitively. Since treatment to the whole pelvis increases the morbidity of treatment, the answer is of the utmost importance.

### Androgen deprivation for high-risk disease

Neoadjuvant and concurrent ADT is generally recommended. RTOG 85-31 demonstrated a significant improvement in disease progression and absolute survival at 10 years with the addition of ADT to standard EBRT whole-pelvis plus cone-down to total doses of between 65 and 70 Gy [26]. Between 1987 and 1992, 977 patients were randomized to goserelin with radiation therapy or at time of relapse. The 10-year survival rate was 49% in the treatment arm versus 39% in the delayed arm ($P = 0.002$). The 10-year local failure rate was 23% in the treatment arm versus 38% in the delayed arm ($P < 0.0001$). Similarly, a randomized Phase III trial of the EORTC showed a significant disease-free survival (DFS) and overall survival in favor of hormone therapy. Between the years 1987 and 1995, 415 patients were randomized to whole-pelvis radiation therapy of 50 Gy plus a 20 Gy prostate cone-down with or without goserelin and cyproterone acetate. At median follow-up of 65.7 months, there was a significantly improved 5-year DFS of 74% versus 40% with the use of hormonal therapy ($P = 0.0001$).

The 5-year overall survival was 78% in the hormone group versus 53% in the radiation therapy alone group ($P = 0.0002$) [27].

## Toxicity profile

### Anatomic considerations

By virtue of its anatomic location, anterior to the rectum and posteroinferior to the bladder, treatment to the prostate results in mainly acute urinary and rectal side-effects. The urethra, running right through the gland, can hardly be avoided. Neurovascular bundles responsible for erectile function run alongside the right and left posterolateral apical aspects of the gland (Figure 134.1). As a result of their location, these structures receive a relatively high dose of radiation therapy and sustain most

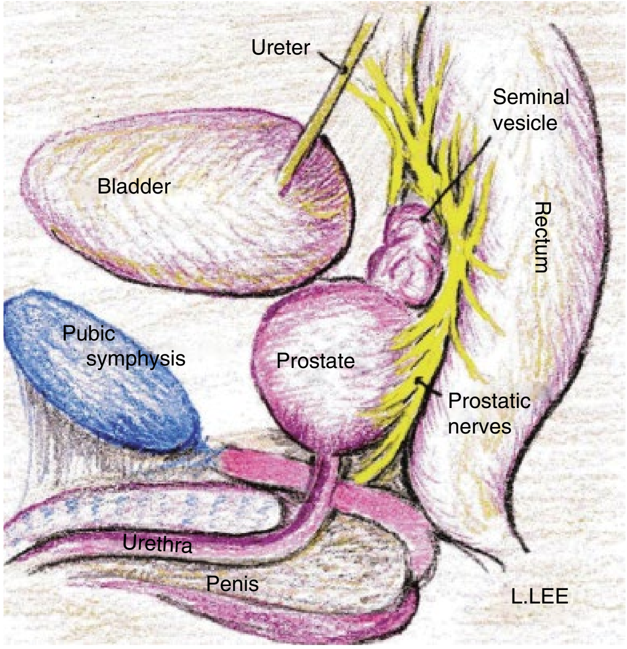

**Figure 134.1** Prostate *in situ*.

of the collateral damage from treatment. Imaging plays a primary role in locating these structures to assist in minimizing the planned dose and also maintaining precision of treatment delivery. The ultimate goal is to improve the therapeutic margin by increasing dose to the prostate, while reducing dose particularly to the bladder and rectum.

## Grading toxic events

The EORTC/RTOG criteria of acute and chronic radiation morbidity are provided for all different clinical systems. Acute morbidities for lower gastrointestinal and genitourinary side-effects, often cited for prostate cancer treatment, are listed in Table 134.4. The criteria for late effects are determined after the 90th day from the commencement of therapy and are listed in Table 134.5 [28]. Common Terminology Criteria for Adverse Events (CTCAE) provide similar information and are also frequently used. Version 4.0, released in May 2009 and updated in September 2009, includes a range of grades for various toxicities. The grading system ranges from 1 to 5: asymptomatic, symptomatic, severely altered function, life-threatening consequences, and death, respectively (Table 134.6). Rectal toxicities include rectal fistula, hemorrhage, mucositis, necrosis, obstruction, pain, perforation, and ulcer. Urinary toxicities include urinary fistula, frequency, incontinence, retention, tract obstruction, tract pain, urgency, cystitis and hematuria. Other adverse events that may apply to prostate cancer treatment include ejaculatory disorder and erectile dysfunction.

### Morbidity data

Current NCCN practice guidelines recommend doses of 75.6–79 Gy for low-risk disease and 78–80 + Gy for intermediate- to high-risk disease. Acute toxicities were reported for 772 patients undergoing IMRT to 81–86.4 Gy

**Table 134.4** Radiation Therapy Oncology Group (RTOG) acute radiation morbidity scoring criteria.

| Score | 0 | 1 | 2 | 3 | 4 |
|---|---|---|---|---|---|
| Lower gastrointestinal | No change | Increased frequency or change in quality of bowel habits not requiring medication/ rectal discomfort not requiring analgesics | Diarrhea requiring parasympatholytic drugs/mucus discharge not necessitating sanitary pads/ rectal or abdominal pain requiring analgesics | Diarrhea requiring parenteral support/ severe mucus or blood discharge necessitating sanitary pads/ abdominal distention (distended bowel loops on radiograph) | Acute or subacute obstruction, fistula or perforation; GI bleeding requiring transfusion; abdominal pain or tenesmus requiring tube decompression or bowel diversion |
| Genitourinary | No change | Frequency of urination or nocturia twice pretreatment Habit/dysuria, urgency not requiring medication | Frequency of urination that is less frequent than every hour Dysuria, urgency, bladder spasm requiring local anesthetic (e.g. phenazopyridine) | Frequency with urgency and nocturia hourly or more frequently/dysuria, pelvic pain or bladder spasm requiring regular frequent narcotic/gross hematuria with/ without clot passage | Hematuria requiring transfusion/acute bladder obstruction not secondary to clot passage, ulceration or necrosis |

**Table 134.5** European Association for Research and Treatment of Cancer (EORTC)/Radiation Therapy Oncology Group (RTOG) criteria of late effects.

| Score | 0 | 1 | 2 | 3 | 4 |
|---|---|---|---|---|---|
| Small/large intestine | None | Mild diarrhea; mild cramping; bowel movements 5 times daily; slight rectal discharge or bleeding | Moderate diarrhea and colic; bowel movement >5 times daily; excessive rectal mucus or intermittent bleeding | Obstruction or bleeding requiring surgery | Necrosis/perforation fistula |
| Bladder | None | Slight epithelial atrophy; minor telangiectasia (microscopic hematuria) | Moderate frequency; generalized telangiectasia; intermittent macroscopic hematuria | Severe frequency and dysuria; severe telangiectasia; frequent hematuria; reduction in bladder capacity (<150 ml) | Necrosis/contracted bladder capacity (<100 ml), severe hemorrhagic cystitis |

**Table 134.6** Common Terminology Criteria for Adverse Events (CTCAE) Version 4.0 grading system.

| Grade refers to the severity of the adverse event: | |
|---|---|
| Grade 1 | Mild; asymptomatic or mild symptoms; clinical or diagnostic observations only; intervention not indicated |
| Grade 2 | Moderate; minimal, local or noninvasive intervention indicated; limiting age-appropriate instrumental activities of daily living (ADL)[a] |
| Grade 3 | Severe or medically significant but not immediately life-threatening; hospitalization or prolongation of hospitalization indicated; disabling; limiting self-care ADL[b] |
| Grade 4 | Life-threatening consequences; urgent intervention indicated |
| Grade 5 | Death related to adverse event |

[a] Instrumental ADL refer to preparing meals, shopping for groceries or clothes, using the telephone, managing money, etc.

[b] Self-care ADL refer to bathing, dressing and undressing, feeding self, using the toilet, taking medications, and not bedridden.

**Table 134.7** Acute toxicity with intensity-modulated radiation therapy (IMRT) to 81–86.4 Gy ($n = 772$).

| Toxicity grade | Gastrointestinal | Genitourinary |
|---|---|---|
| 0 | 568 (74%) | 258 (33%) |
| 1 | 169 (22%) | 296 (38%) |
| 2 | 35 (4%) | 217 (28%) |
| 3 | 0 | 1 |

**Table 134.8** Late toxicity intensity-modulated radiation therapy (IMRT) to 81–86.4 Gy ($n = 772$).

| Toxicity grade | Gastrointestinal | Genitourinary |
|---|---|---|
| 0 | 688 (89%) | 570 (74%) |
| 1 | 69 (9%) | 121 (16%) |
| 2 | 11 (1.5%) | 76 (9.5%) |
| 3 | 4 (0.5%) | 5 (0.5%) |

between the years 1996 and 2001 (Table 134.7). These doses are at the upper end of the recommended dose spectrum and they resulted in relatively low morbidity. Most patients developed grade 0–1 acute toxicity and there was one grade 3 urinary complication of obstruction. Late toxicity is shown in Table 134.8. With a median follow-up of 24 months, most patients had no residual gastrointestinal symptoms (89%) and many had no urinary symptoms (74%). At a median of nine months, 1.5% had developed grade 2 rectal bleeding and 0.5% grade 3 bleeding requiring transfusion or laser cauterization. At a median of six months, 9.5% had developed grade 2 chronic urethritis requiring medication for symptom control and 0.5% grade 3 urethral stricture requiring dilation. Among the 540 patients who were potent prior to treatment, 52% maintained erectile function at 2 years post treatment [29]. Longer follow-up will be important for documenting chronic toxicity at these doses. For patients treated between 1988 and 2000 to 66–81 Gy using either 3D conformal techniques or IMRT, CTCAE criteria were reported for a median 10-year follow-up. The 10-year actuarial incidence of grade 2 or greater gastrointestinal toxicity was 9% and of genitourinary toxicity was 15%. The use of IMRT reduced the incidence of proctitis from 13% to 5% ($P > 0.001$) [30].

## Quality of life

A prospective study examining acute and late toxicity and QOL up to 18 months after IMRT to 76 Gy showed similar findings to the morbidity data reported above and acceptable QOL. Acute urinary grade 2 and 3 toxicity was 38% and 2%, respectively. Acute bowel grade 2 and 3 toxicity was 13% and 0%, respectively. Temporary detriment in QOL, mainly due to urinary symptoms, reverted back to initial scores by 18 months [31]. A QOL comparison of treatment with 3D conformal therapy to 70 Gy versus IMRT to 76 Gy using fiducial markers to verify position, showed no detriment for the higher dose using IMRT at 1 and 6 months after treatment. There was actually an improvement in pain and urinary symptoms within the first month [32]. These techniques are detailed in the section on Treatment planning.

### Secondary malignancies

Secondary malignancies are a rare but dreaded complication of therapeutic ionizing radiation. A secondary malignancy is characterized by occurrence within the prior radiation portal and usually has a latency of several years or longer, especially for solid tumors. The potential for developing secondary malignancies is generally greater for a younger patient because of the likelihood of longer survival compared to an older patient. Surveillance, Epidemiology, and End Results (SEER) data comparing over 50 000 patients treated with radiotherapy and over 70 000 patients treated with surgery for prostate cancer, showed a small but statistically increased risk of developing tumors of the bladder, rectum, and lung, and also sarcoma. There was an increased relative risk of 15% for patients surviving 5 years or more, and 34% for patient surviving 10 years or more. The absolute risk of developing a secondary malignancy from radiation therapy was 1 in 290 patients, increasing to 1 in 70 for those surviving 10 years or more [33]. These data are consistent with other reports [34–37]. When brachytherapy is examined separately, the risk does not appear to be as for EBRT [35, 37]. Therefore, if otherwise reasonable, brachytherapy may be a better choice for the younger patient.

## Treatment planning

### Simulation details

Treatment planning begins with a simulation. The patient is positioned for the treatment and immobilization devices are used to ensure that the patient's position is reproducible on a daily basis. These may include a thermoplastic mold stretched over the pelvis and secured to the table. Various techniques to identify certain structures, such as a Foley catheter and rectal catheter, or contrast dye may be useful to define the bladder and rectal margins. Comfort measures such as a hand ring or wedge under the knees may be offered. Kilovoltage (kV) X-rays, generally a set of orthogonal films overlain with a grid, are obtained at the time of simulation and serve as the baseline for future setup verification. Tattoos are placed on the skin at the center of the anterior and two lateral fields in order to "triangulate" the isocenter. In the traditional four-field box technique, treatment was from anterior, posterior, right lateral, and left lateral directions (Figure 134.2). Field borders were designated on the films and generally corresponded to bone landmarks (e.g. the inferior border was set at the bottom of the ischial tuberosities). Cerrobend, a lead alloy, was constructed in blocks as

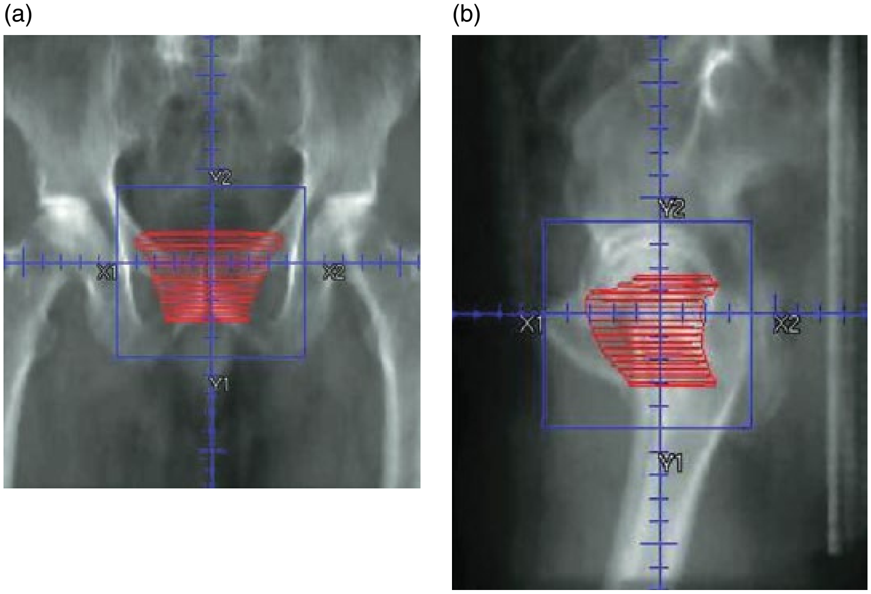

**Figure 134.2** (a, b) Examples of anterior and lateral beam appearance from four-field box technique.

needed (e.g. to shield the posterior rectum based on the configuration of the rectal contrast on the film). Currently, ball bearings are placed on the tattoos and a CT scan of the pelvis is obtained instead of X-ray films. Digitally reconstructed radiographs (DRRs) are generated from the CT information (Figure 134.3).

## Portal imaging

The traditional method of checking a patient's setup during treatment is weekly megavoltage (MV) portal imaging. This involves obtaining a set of orthogonal films, using the skin tattoos to locate the isocenter. These images utilize the MV energy of the treatment itself, which provides films of poor quality, but which are generally suitable for visualizing the bone anatomy. More recently, kV, or diagnostic quality imaging, is now commonly available with modern linear accelerators. When overlain with a grid, these portal images can be compared with the initial set of therapeutic-quality simulation films or DRRs obtained at the beginning of treatment to verify the patient's position (Figure 134.4). Cone-beam CT scans are also available with modern treatment machines, further improving the ability to localize and reproducibly treat the prostate.

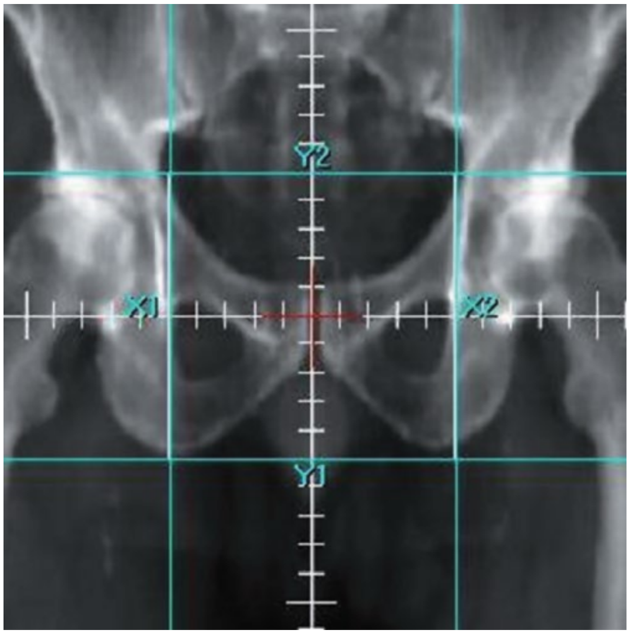

**Figure 134.3** Digitally reconstructed radiograph.

## Target volume delineation

The CT images are reviewed using treatment-planning software, many of which are commercially available. The area of interest is outlined on each slice to generate a target volume. Target volumes generally include a gross tumor volume (GTV), a clinical target volume (CTV) which includes areas at high risk for occult microscopic disease, and a planning target volume (PTV), which includes the CTV with a margin for motion and setup error. For the treatment of prostate cancer, the CTV rather than the GTV is usually outlined. The CTV is generally the prostate gland and some portion of the seminal vesicles (general rules of thumb is proximal third for low-risk disease, proximal two-thirds for intermediate risk, and the whole seminal vesicle for high risk). Recent investigations have demonstrated promising early results for focal or partial gland therapy and for integrated boosts to areas of gross intraprostatic disease, but these approaches are too immature to be considered standard of care. MRI has played an important role in the identification of intraprostatic and extraprostatic disease that should be covered in standard radiation fields. Image fusions with deformable registration technologies are typically integrated into the radiotherapy planning process. The PTV is often represented by a volume that is

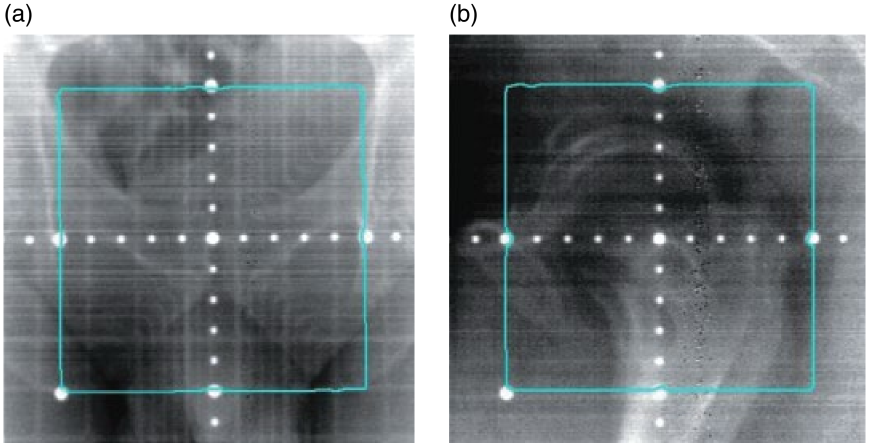

**Figure 134.4** (a, b) Orthogonal portal images for prostate treatment verification.

generated by expanding the prostate volume in all dimensions. Differential margins are often used. With modern IGRT techniques discussed later, it is possible to minimize the PTV margins to the order of 5–7 mm for conventionally fractionated IG-IMRT and even less for SBRT.

### Three-dimensional conformal radiation therapy

Three-dimensional conformal radiation therapy improved upon the traditional four-field box technique but is now generally outdated for modern prostate cancer radiotherapy. CT information obtained at the time of simulation allows an unlimited variety of beams to be chosen to optimize treatment delivery. A typical plan might use five to seven beam angles to target the prostate while avoiding the bladder, rectum, and femoral heads (Figure 134.5). Differential weighting or adjusting the fractional dose per beam fine tunes the coverage of the target volume. Various techniques for beam collimation were employed, including the use of cerrobend blocks, wedges, and multileaf collimators. Examples of two oblique fields of a six-field plan with blocking around PTV is shown in Figure 134.6.

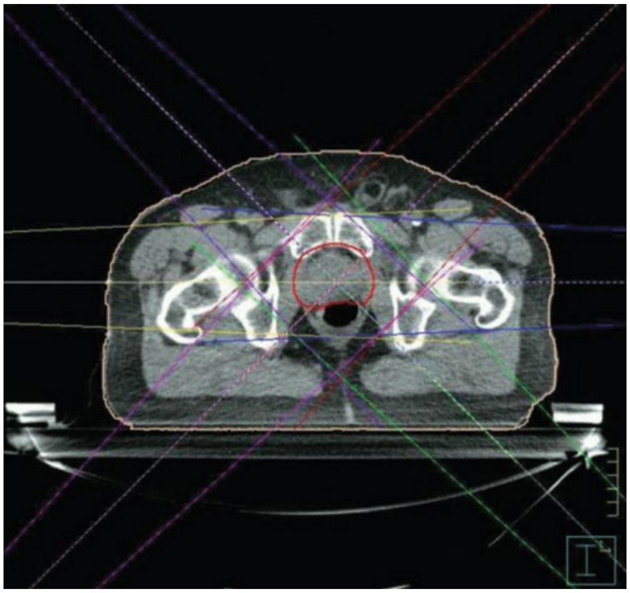

Figure 134.5 Axial slice of six-field 3D conformal plan.

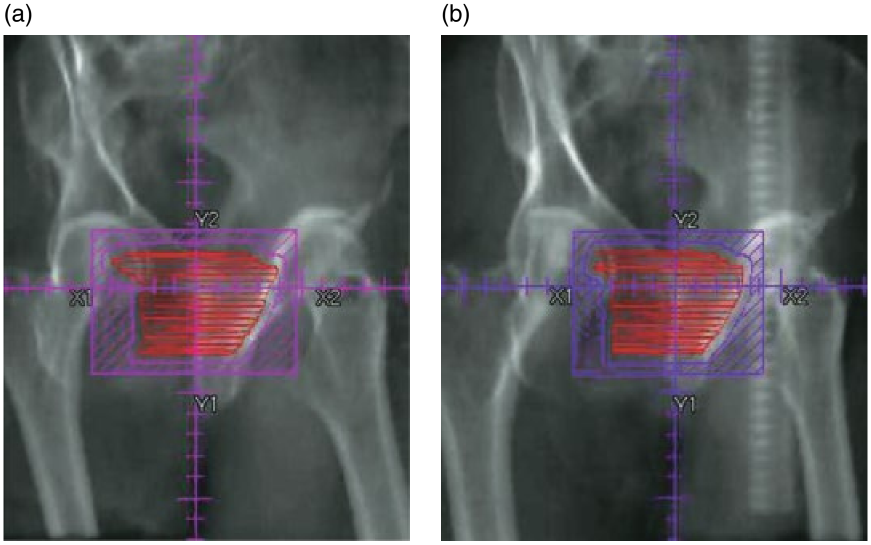
### Rectal dose–volume relationships

Rectal dose–volume relationships have been studied in detail. The percentage of rectal volume receiving 70 Gy ($V_{70}$) predicts for chronic toxicity. In one study the rectal doses of 331 patients undergoing 3D conformal radiation therapy to 75.6 Gy were analyzed. With a median follow-up of 1.6 years, a $V_{70}$ of less than 25%, 25–40%, and greater than 40% resulted in grade 2 or greater toxicity rates of 9%, 18%, and 25% respectively [38]. A similar analysis was done on 163 patients treated with 3D conformal techniques to 74–78 Gy and a median follow-up of 62 months. The 6-year rate of rectal complications of grade 2 or higher was 54% versus 15% for $V_{70}$ of greater than 26.2% versus 26.2% or smaller, respectively [39]. Further analysis showed that even at lower doses, high volume resulted in increased toxicity. There was a 50% or higher incidence of grade 2 toxicity or worse within 2 years if 80% or more of the rectal wall was exposed to 32 Gy [40]. These and other data allowed limits to be set for future treatment planning. These limits are generally achievable with IMRT.

Figure 134.6 (a, b) Examples of two oblique fields of a six-field plan with blocking around planning target volume (PTV) shown in red.



### Intensity-modulated radiation therapy

The advent of IMRT in the mid 1980s revolutionized modern radiotherapy. IMRT expands on the simple wedges used to provide a gradual dose gradient across a field. This technique is coupled with powerful computer planning algorithms and utilizes a series of miniature sliding doors, called mutlileaf collimators (MLCs), which differentially attenuate the radiation beam. Since the MLCs can remain open or closed in innumerable positions, the ability to collimate the radiation beam is vastly improved.

## Treatment delivery

### Setup uncertainty and rectal variability

Traditional methods of orthogonal portal images and skin tattoos lead to margin uncertainties as large as 1–2 cm [41]. Positioning based on bone anatomy is clearly limited in its ability to reproduce organ position. This could be addressed by increasing the margins, but in the area of the prostate, increased margins lead to increased complications [42]. A study of weekly CT scans on six patients showed significant interfraction target position variability. Estimates of PTV margins in the anteroposterior (AP), craniocaudal (CC), and mediolateral (ML) directions to cover the CTV with 95% certainty were: 12.4 mm, 10.3 mm, and 5.6 mm, respectively, for the prostate, and 13.8 mm, 8.6 mm, and 3.9 mm, respectively, for the seminal vesicles [43]. Rectal variability is reproducible and appears to be responsible for most of the variation [44, 45]. For example, the prostate may be located posteriorly if a patient has diarrhea and less rectal filling. On the other hand, the prostate may be located more anteriorly if the patient has proctitis, a full rectal vault, or tends to tense the pelvic muscles during treatment. Therefore, corrections are not universal and ideally should be tailored to the individual.

### Bladder volume

The bladder appears to contribute less to target position variability than the rectum [43]. An empty bladder is more reproducible than a full bladder, but allows a larger volume of bladder to be exposed to the high-dose area. Conformal treatments such as IMRT can reduce bladder volume significantly. Patients can also be treated with a full bladder, but this state tends to be less reproducible with variable bladder volumes from day to day. In addition, the patient may tense the pelvic muscles to postpone urination, which may lead to changes in prostate position [41]. However, if the patient can train himself to have a consistently full bladder for treatment each day, the major advantage is that a significantly smaller volume of bladder will be in the high-dose area.

### Intrafraction error

Intrafraction error, which occurs during a single treatment, dramatically increases the complexity of target motion. Although breathing can result in predictable sinusoidal patterns, motion in the region of the prostate has been described as “slow drift” or “sudden transient” due to acute changes in colonic content [46]. A study of 21 patients was conducted where a CT was done before and after treatments to determine the intrafraction error. Prostate drifts of greater than 5 mm were found in 12% of all fractions, and a margin of 6 mm was determined to compensate for these changes [47]. These unpredictable movements suggest a benefit to localization and tracking the prostate during treatment. IGRT includes various methods to achieve these goals.

## Methods for image-guided radiation therapy

### Placement of fiducials

Fiducial markers are usually made out of metal and vary in size and configuration. Commonly used fiducials are made of gold and can be shaped like pellets or coils. For the prostate, gold fiducials usually measure less than 1 mm in diameter and a few millimeters in length. A textured surface, as with the coils, can reduce migration. Preparation for the procedure includes an enema the night before and on the morning of the procedure. Antibiotics are prescribed prophylactically to prevent infection. For example, ciprofloxacin 500 mg may be taken twice a day for 3 days. When the implantation site is identified on rectal ultrasound, approximately 1–3 ml of lidocaine 1% is injected for local anesthesia. The fiducials are placed into an introducer needle and then placed into the site with a stylet. Toxicity is generally minor, including bleeding such as hematuria, hematospermia, and hematochezia; generally lasting for a day or two. There may be mild rectal discomfort, which is usually improved with acetaminophen. Sepsis is also a possibility, but rare.

### On-board imaging

A logical advance in weekly portal imaging is to use therapeutic-quality X-rays so that the images are closer in quality to the simulation films. A kV X-ray tube mounted opposite an image detector is conveniently added to any existing linear accelerator, and is otherwise known as on-board imaging (OBI). The high resolution allows for better visualization of skeletal anatomy and also of fiducials implanted in soft tissues. An additional benefit of this system is a significantly lower dose of radiation, about 0.01–0.1 cGy/film; MV imaging gives an estimated 4–16 cGy/orthogonal pair [48]. The lower dose given with kV images makes daily imaging for localization more reasonable. In order to make the process of daily filming time efficient, an electronic portal imaging device (EPID) is often used rather than traditional film processing. In addition, a kV fluoroscopy unit can be used to localize fiducials at the start of treatment, and then can provide real-time tracking of the fiducials during treatment [49]. The treatment may be held if the fiducials move out of a predetermined volumetric range, then restarted when the fiducials move back into range. This process is referred to as gating and can be used with other real-time tracking techniques.

## CT-based verification

Since CT-based planning has become the norm for 3D conformal and IMRT planning, using CT for verification is a logical advance. CT provides soft tissue detail and a 3D aspect to verification, a clear improvement upon the traditional 2D orthogonal films. CT-based verification may utilize either kV or MV energies. The pros and cons of these are similar to those for the respective X-ray films. The images can also be obtained using either a helical beam or a large field cone-beam. The helical beam opposite the detector makes multiple rotations around the patient in order to obtain the necessary data to construct the images. The large field cone-beam is opposite a flat panel detector, which can acquire the data in a single rotation [43].

Cone-beam MV CT utilizes the treatment beam itself to provide the images. The system is easy to implement since it only requires an EPID mounted onto an existing machine. The wide field beam is subject to divergence and scatter, which reduces the quality of the images. The dose to the patient is relatively high, approximately 5–15 cGy/scan [50]. Helical MV CT (TomoTherapy, Madison, WI, USA) is a combined CT scanner and linear accelerator that utilizes the continuous motion of the gantry and couch of a diagnostic helical CT scanner to provide both imaging and treatment. It exposes the patient to less radiation, about 1–2 cGy, but it may take longer to acquire the necessary images since multiple rotations around the patient are needed to complete the process. As a result, the images are more likely to show motion artifact due to respiration. Although poor relative to kV images, the image quality of MV CT is sufficient for positioning corrections based on skeletal anatomy. A primary advantage to using MV CT is the reduced artifact from orthopedic hardware [43]. This can be useful for patients with a hip prosthesis. It is particularly useful for visualizing fiducials because of the lack of a star-like artifact that can be present in kV images. Compared to kV imaging, the disadvantages include poorer anatomic image quality and increased dose to the patient.

A kV CT system provides excellent resolution since the CT is of diagnostic quality and is actively under investigation for advances in image adaptive techniques. For example, head and neck tumors have the potential to change rapidly in size during treatment and are often surrounded by multiple soft tissue organs of interest, such as the parotid glands and spinal cord. The CT information used for verification can be used not only to realign the patient, but also to replan the treatment if there are major anatomic differences. The system may be more difficult to implement than MV CT since it requires a CT unit separate from the linear accelerator. Moreover, the patient must remain immobilized in the treatment position for both scans. With a 180° couch rotation, the patient can be moved from the linear accelerator to the mobile CT unit, which then can be moved into position for the scan.

Kilovoltage cone-beam CT can offer several advantages, including superior imaging as well as real-time tracking ability from the fluoroscopic capability. A kV unit is mounted 90° from the gantry of the linear accelerator and opposite an X-ray detector. Submillimeter accuracy has been reported with this system. Since the image registration requires a full rotation over a period of about 1 minute, the system can still be subject to inaccuracies from breathing and other motions. The system is well-suited for intracranial radiosurgery but may require gating techniques for lung tumors.

## Ultrasound verification

The B-mode Acquisition and Targeting System (BATS) is a portable ultrasound localization device. CT data from the simulation are transferred to the system. Ultrasound imaging is performed prior to treatment and matched to the original CT images. If the images differ, the system will then produce the necessary couch shifts in order to realign the patient to match the ultrasound real-time images [51]. Despite the ease of implementation, accuracy may not be as high as with CT verification techniques due to the lower image quality and the potential for the probe itself to move the prostate [52, 53]. Therefore, the technique is more dependent on user skill and interpretation of images. One major disadvantage is the lack of tracking ability.

## Electromagnetic field tracking

A major advantage to electromagnetic field tracking is the lack of additional ionizing radiation. The Calypso 4D Localization System (Calypso Medical Technologies, Seattle, WA, USA) requires the implantation of beacon transponders, which carries the same risks as implantation of fiducials. Although anatomic images are not produced, the corrections are objective and do not require user skill and interpretation.

### Transponder placement

The beacon transponder contains a miniature electrical circuit sealed in a glass capsule, measuring 1.85 mm in diameter and 8 mm in length (Figure 134.7). Like fiducials, transponders are implanted into the left lobe, right lobe, and apex of the prostate gland via 14G introducer needles. Transponders may migrate soon after the procedure. The mean of the standard deviation of intertransponder distance variation measured at 4 days after implantation was 1.3 mm and 0.8 mm at 14 days after implantation [54, 55]. This compares favorably to gold seed markers, for which the mean of the standard deviation of intermarker distance variation measured throughout the course of treatment was 1.0 mm [56]. Like fiducials, beacons may become lost due to implantation into the urethra or into the venous plexus going to the seminal vesicles, but in the majority of cases they are quite stable. Another potential route for loss of a transponder located between the prostate and rectum could be through the rectal wall. In 60 patients, one study reported loss of one beacon via the urethra and one to the venous plexus [55]. The mean standard deviation of the intertransponder distances over a period from 4 days post implant through the last radiation fraction was 0.8 mm. There was no significant difference in the stability of the transponders placed at the base versus the apex [57]. Overall, these data demonstrate significant stability of the geometry of implanted transponders throughout an entire course of EBRT, which is typically 8–9 weeks.

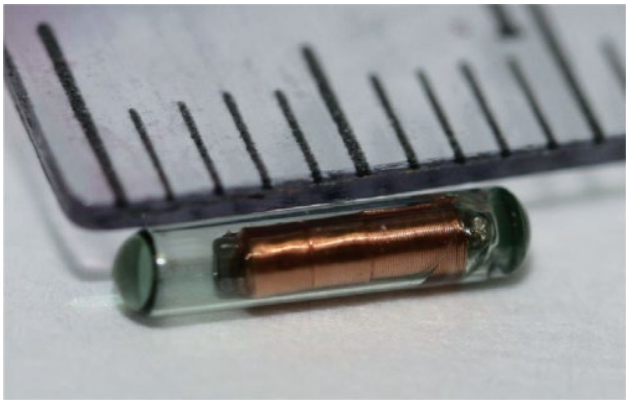


**Figure 134.7** Close up of Calypso (Calypso Medical Technologies, Seattle, WA, USA) beacon transponder next to millimeter ruler demonstrating internal electromagnetic coils.

### Simulation procedure

The patient then returns for simulation about 1–2 weeks later. Patients are supine for the simulation, and CT scan slices of 1–1.5 mm of the pelvis are obtained. Previous work has shown that transponder locations are known to within 0.7 mm using thin-slice CT. Immobilization devices are generally minimal. The treatment-planning CT is done as usual and the isocenter is placed in the middle of the beacons. Then the coordinates of the beacons in reference to the isocenter are entered into the Calypso software.

### Localization

When the patient is ready to be treated, the beacon transponders are located, which includes identifying their positions in 3D space relative to each other. An electromagnetic array, containing source and receiver coils, is placed over the patient. The source coils emit an electromagnetic signal that excites the beacon transponders. The signal is then turned off, and the receiver coils then detect the signal emitted from the transponders. Each transponder has a unique resonant frequency so that each one can be distinguished from the others. A best geometric fit is determined to match the coordinates from the simulation data entered previously into the system. This correction is translated into couch movements, which will move the patient to the corrected position. When a patient is set up with skin tattoos and verified with the Calypso system, most of the corrections are within 1.5 cm, but approximately 10% are greater than 1.5 cm, demonstrating the value of localization. Compared with the kV X-ray localization methods, the accuracy of the Calypso system is less than 1.5 mm.

### Tracking

For tracking, position updates are obtained at 10 Hz frequency and the differences between the actual isocenter and the calculated isocenter are displayed graphically, providing the fourth dimension of time (Figure 134.8). If the movement is outside a set threshold of, for example, 3 mm, then the operator has the option of stopping the treatment until the target is back in alignment, or performing a couch correction if needed. Most of the lateral shifts are within 5 mm but about 8% exceed 1 cm. Large lateral shifts tend to be more common in large patients.

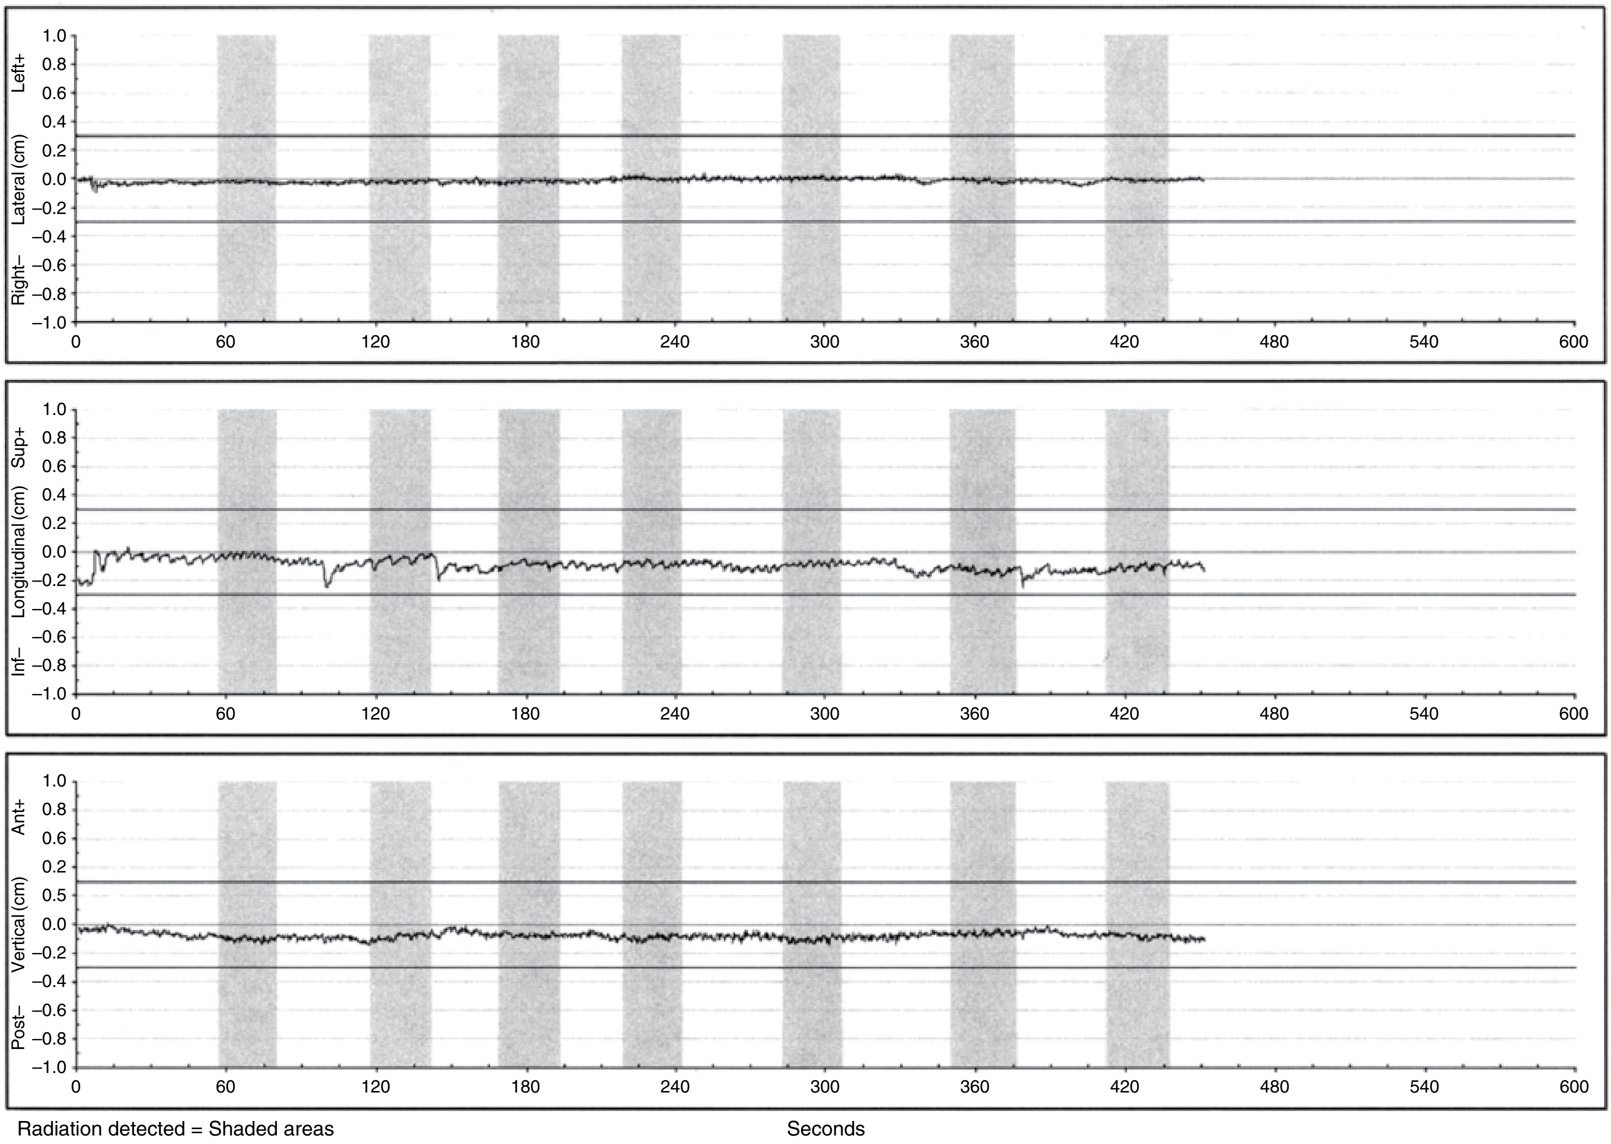

**Figure 134.8** Calypso session report showing patient remaining within set threshold; gray areas represent when the radiation is turned on.

Superoinferior shifts tend to be within 5 mm, suggesting relatively limited movement in these directions. Anteroposterior shifts, depending on rectal contents, are most common and are usually within 1.5 cm. Tracking data show that motion of more than 5 mm for longer than 30 seconds occurs during 15% of the fractions [56]. With the exception of a slow posterior shift associated with relaxation, many of these movements are unpredictable and pose a challenging problem for future improvements and developments.

## Conclusions

IGRT offers a wide range of techniques, which allow an improved therapeutic ratio in the treatment of prostate cancer by increasing the dose to the tumor for better tumor control, while reducing the dose to adjacent critical organs for lower morbidity. This goal drives much of the research performed in the field of radiation medicine and promises to improve outcomes and QOL for patients.

## Introduction

Since 1998, prostate cancer has been the most prevalent malignancy in men in the United Kingdom [1]. As a malignancy, its mortality is second only to that of lung cancer [1]. With any cancer, the optimal end goal is to cure or control the disease with minimal side-effects or complications. To achieve this, one must balance the number of quality years of life gained against any potential morbidity of any particular treatment and appropriately match that to the risk that any particular cancer poses to a patient. This creates an immediate dilemma in prostate cancer. This particular malignancy often has a long natural history before culminating in lethality, even in the absence of treatment, and hence there is often innate difficulty when deciding whether or not treatment is necessary in a particular treatment, and if it is, in what manner should that treatment be advocated? Such a conundrum in prostate cancer is further compounded by the intrinsic urinary and sexual side-effects that are associated with our treatment armory and which many men find displeasing. Furthermore, an increasingly easy access to prostate specific antigen (PSA) screening has led to a clear downward stage migration at diagnosis, with contemporary men being much more likely to be diagnosed at earlier, organ-confined stages [2]. Nevertheless, many men with low- and intermediate-risk disease will inevitably choose curative therapy rather than active surveillance [3–5]. There is no single cause for such decisions. They are likely due to both the psychological impact of a diagnosis of malignancy and the psychological burden of active surveillance for men alongside a physician's concern over potential disease progression. Thus, despite many of these men having disease which would be unlikely to impact their life expectancy they elect to undergo radical treatments which, despite their excellent curative potential, carry significant urological and sexual morbidity.

In contemporary surgical practice, there is an evident movement toward the use of increasingly minimally invasive techniques. Within prostate cancer this is clearly demonstrated by the recent introduction of new laparoscopic and robotic-assisted techniques. In addition, novel techniques such as high-intensity focused ultrasound (HIFU), cryotherapy, and radiofrequency ablation (RFA) offer a more discrete delivery of treatment and allow for a cancer to be destroyed along with a margin of healthy tissue rather than an inevitable destruction of the entire gland. Such an approach confers a reduction in the side-effect and complication potential seen after established radical therapies. These novel techniques represent an additional therapeutic choice for men with low- to intermediate-risk disease in whom the side-effects of radical therapies are unacceptable despite their excellent curative potential [6]. Because of this, the existence of a clinical niche, which offers curative intent alongside reduced side-effects, is undeniable. Such a niche is not isolated within the field of prostate cancer. For example, wide local excision for ductal breast carcinoma has clearly replaced the radical mastectomy, along with its defeminizing side-effects, as the treatment of choice in localized disease, from both the patient and physician perspective [7]. Clearly, there is a valid comparison to be made here with the sexual side-effect profile associated with the radical treatment options in prostate cancer.

Such techniques are potentially very attractive when used as focal therapies. Most prostate cancers are multifocal, however, around 15–20% are unifocal [8]. In addition, the concept of an index lesion, usually the most

voluminous and highest grade, which drives the metastatic process forward, leaving its less aggressive counterparts as spectators, has been proposed [8]. These oncological characteristics allow for a defined treatment of a defined area, offering good curative rates and a less severe side-effect profile when compared to radical therapies. Such a combination, as described by the Consensus Conference of Focal Treatment of Prostatic Carcinoma as “an individualized treatment that selectively ablates known disease and preserves existing functions, with the overall objective of minimizing lifetime morbidity without compromising life expectancy” [9] is the ultimate goal.

However, as we currently stand, a universally accepted set of indications for focal treatments of prostate cancer is still lacking. Patient suitability is based on their risk of bilateral or extraprostatic disease, and decisions made with guidance, such as that proposed by the National Comprehensive Cancer Network and advocated by the 2015 consensus meeting on focal therapy [10], which are based on clinical, radiological, and histological findings.

Although there are an increasing number of focal treatments available – HIFU, cryotherapy, RFA, photodynamic therapy, focal laser ablation, and injectable toxins – for the purpose of this text we will focus on HIFU of the prostate and its role in the treatment of prostate cancer.

## High-intensity focused ultrasound for prostate cancer

Since the early 1930s, we have known that HIFU has the ability to destroy living tissue [11]. However, at the time of this discovery, the existing imaging technology available was simply inadequate and it would be some time before cross-sectional computed tomography (CT) or magnetic resonance imaging (MRI) was in regular use. Likewise, diagnostic ultrasound imaging was not yet even in its infancy and because of this the use of HIFU remained obscure, along with the intraprostatic lesions that were unable to be identified accurately or treated. However, the translational potential of HIFU as an ablative technology was further explored in the 1970s and 1980s [12, 13]. After some conceptual success there was a natural move to assess its potential as a therapy for use in malignancies. In particular, the urological community was an especially prominent proponent and since the 1990s numerous highly accurate commercially available devices were developed. In some uro-oncology centers the technique is in regular use for the noninvasive, focal or salvage treatment of prostatic carcinoma.

Ultrasound is an inaudible (to humans) high-frequency mechanical vibration wave that in clinical practice is emitted by a transducer. The ultrasound waves are absorbed by the prostatic tissue and agitate the molecules within [14]. The consequential friction generates heat that can cause the temperature within the affected area to rise to above 80°C in a matter of seconds [14]. The lower frequency ultrasound waves utilized by HIFU, when focused precisely on a single point, result in tissue destruction by coagulative necrosis induced by cavitation and heat injury [14]. The heat causes denaturation of lipoprotein and protein structures in the sarcolemma and the intracellular organelles and associated machinery contained within [15]. Cavitation is a destructive mechanism caused by microbubble formation and collapse in targeted tissue, which causes further tissue destruction [16].

The aim of HIFU is the irreversible destruction of prostatic tissue. This is achieved by the focused deposition of energy on a single point within the gland. This increases the temperature within that minimal area to a degree sufficient to cause discrete destruction of tissue [13, 14]. Mechanically, in order to achieve this, HIFU generally uses ultrasound frequencies of 0.5–7.0 Hz, in comparison to the frequencies of 2.0–12.0 Hz more usually used [17]. Thus, the energy levels delivered to the tissue in a focused HIFU beam are typically 10 000 times greater than a modern diagnostic ultrasound beam [18]. This level of energy rapidly increases the temperature of the beam’s focal point to over 80°C. Such a temperature is more than adequate to induce cell death [14]. However, outside of the focal point, little tissue damage occurs due to a rapid drop-off in temperature. The resultant post-HIFU lesion shape and volume is dependent on the design of the transducer, the “on” and “off” time of the beam and the power (W) that is delivered [19]. This focus of discrete destruction is small in volume but reproducible. Each pulsed cycle of energy results in a rice-shaped ellipsoid (3 mm × 3 mm × 10 mm) of ablation [20]. This can be repeated by refocusing the piezoelectric crystals on further areas of prostatic tissue until the desired predefined treatment area has been fully treated.

The safety and efficacy of HIFU is vital if effective treatment is to be achieved. A key part of this quality control is optimal intraoperative monitoring, which both accurately targets disease and actively monitors the effects of treatment. Currently, either ultrasound or MRI may be used to monitor HIFU treatment [21, 22]. However, given the mobility and accessibility of ultrasound and the significantly higher costs of MRI, the former modalities are clearly the more popular choice. Usually, the imaging ultrasound transducer is mounted in the treatment probe, making real-time intraoperative monitoring possible. The intraoperative gray-scale image can be monitored for hyperechoic changes (Uchida changes) [22], which represent microbubble formation (in effect, steam) [23] and the operator can react to them accordingly. However, this can also be a disadvantage as the bubbles cause appreciable ultrasound artifacts that confer additional difficulty to the interpretation of often already poor-quality images [24]. This is of particular concern when tissue in front of the target zone is being treated.

Both *in vitro* and *in vivo* studies have demonstrated that HIFU can target and destroy prostatic malignancies transrectally without inducing metastatic spread [25, 26]. When planning treatment, physical parameters that should be considered include ultrasound frequency (MHz), energy intensity (W), its duration of action and the interval between pulses [11]. In addition, the architecture of the prostate and the location of lesions pose additional difficulties. Because of this, the distance between lesions and the penetration depth should be considered when planning treatment. Current HIFU devices are typically equipped with transducers with adjustable focusing systems. These are moved mechanically, and allow for a large volume of prostate tissue to be treated in a single treatment session [27, 28].

## HIFU treatment devices

Currently, there are two existing commonly used commercially available devices for use in the treatment of prostate cancer: the Sonablate® system (Sonacare Inc., Indiana, IL, USA) and the Ablatherm® HIFU device (EDAP TMS, Lyon, France). Other prototype devices in various changes of development exist, but they are not in common clinical use outside of clinical trials.

The Sonablate device is minimally invasive and mobile (Figure 135.1) with an operating frequency of 4 MHz that has been developed to treat prostate cancer via an endorectal probe (Figure 135.2). The endorectal probe has the advantage of real-time imaging of the prostate during treatment and also has an added option of ultrasound/multiparametric MRI (mpMRI) fusion. This combined imaging and treatment allows the operator to view the treatment effect following each treatment cycle. Furthermore, monitoring of the rectal wall temperature is incorporated within the system which, along with the cooling system (Figure 135.3), gives an added degree of safety and the user interface has been developed to allow for accurate treatment planning and monitoring (Figure 135.4). Using this interface, the operator can acutely target the intended treatment area and adjust the depth of the wave penetration to 3 cm, 4 cm, or 4.5 cm [29]. The energy delivered to the tissue can be monitored by color changes viewed within the targeted area, which allows for a great degree of clarity regarding target accuracy and the cell death contained within.

The Ablatherm device is a semi-automated device that also treats prostate cancer via an endorectal probe; however, the patient must be positioned in the right lateral cubitus position [30]. The unit consists of a treatment module (Figure 135.5), a control module (Figure 135.6) and the endorectal probe (Figure 135.7). The probe contains both imaging and treatment ultrasound transducers

and therefore allows for accurate treatment planning and offers real-time intraoperative imaging with real-time energy delivery adjustments [30]. This combination allows for highly precise energy delivery that creates posttreatment lesions 19–26 mm in diameter, determined by predefined power protocols. Safety features are incorporated and include a patient-monitoring device, real-time rectal wall temperature monitoring, and a rectal cooling system [30]. When this device is used, the HIFU treatment is often combined with transurethral resection of the prostate in order to reduce prostatic volume and the subsequent risk of stricture formation.

## Indications

The most accepted clinical use for HIFU is in patients with localized prostate cancer. These patients either profess a preference for focal therapy due to personally finding the side-effects of radical therapy unacceptable, or they are unfit for radical surgery [11]. However, as focal therapy moves from its infancy to adolescence, our greater clinical experience and conclusions from research have demonstrated clearer safety and efficacy and as such these indications have clearly broadened in scope. Currently, HIFU is indicated in focal therapy for low- to intermediate-risk prostate cancer [31] as well as salvage treatment in radiorecurrent disease [32]. Furthermore, the lesion to be treated should be visible on mpMRI and concordant with histopathological analysis. Importantly, if the disease is to be treated, it should be clinically significant (i.e. the lesion should have a histological Gleason score of 3 + 4 or higher and a volume of greater than 0.2 ml). Contraindications to HIFU are relatively limited but include an absent or severely strictured rectum or a damaged rectal wall [10].

## The procedure

First, the procedure must be planned in advance of the surgery. An mpMRI should demonstrate a visible lesion that is concordant with histopathology. The mpMRI is then used to map the pattern of disease from which a treatment plan is devised, taking the form of a zonal ablation (demonstrated in Figure 135.8). The intension is to destroy the target lesion while preserving as much healthy tissue as is possible.

Unless there are perioperative concerns or a patient's comorbidities demand otherwise, treatment with HIFU is performed as day-case surgery. Full bowel preparation is unnecessary, but an enema an hour prior to the procedure will usually be sufficient to optimize perioperative ultrasound imaging. In general, antimicrobial prophylaxis is unnecessary, but this should be guided by local policy and sensitivities. Intravenous broad-spectrum, Gram-negative, and anaerobic cover is acceptable and furthermore a postoperative course of oral antibiotics is recommended.

HIFU should be performed under general or spinal anesthetic. The latter will require deep sedation as any untoward patient movement renders the treatment significantly more difficult. Furthermore, if there is evident heavy breathing and this is causing movement of the prostate, the patient should be paralyzed and mechanically ventilated.

Once the anesthetic induction is completed successfully, the patient is either placed into the right lateral decubitus position (Ablatherm), or the extended lithotomy position (Sonablate) and the perineum exposed. A urethral catheter may be inserted to help with treatment planning by giving an obvious landmark on ultrasound imaging. This may be removed prior to starting treatment. Suprapubic catheters are an acceptable alternative preferred by some surgeons, and in certain circumstances necessary; however, naturally they carry their own complications. Following this, a digital rectal examination – sometimes augmented by a proctoscope – is performed to ensure an

empty rectum and the endorectal HIFU treatment probe is introduced to the rectum. The position of the probe should be manipulated until the ultrasound images are satisfactory. Once this is acceptable, the prostate can be mapped and the treatment zone defined. The rectal cooling system is then started and the treatment begins. The operator carefully monitors the treatment area, rectal wall distance, reflectivity index, and any reverberations on the user interface to ensure safe delivery of the treatment. If there is concern that structures such as the rectum are at danger of injury, or if any swelling has altered the position of the treatment zone, the treatment can be stopped. The rate of energy delivery (power) differs between devices. It can either be preset (Ablatherm), or it can be changed intraoperatively (Sonablate), dependent on tissue changes observed

during treatment. A standard urethral catheter should be left in place for between 5 and 10 days.

Usually, patients are discharged on the day of surgery. Antibiotics are prescribed as discussed previously. In addition, alpha-blockers are given for 14 days post procedure to reduce postoperative lower urinary tract symptoms and the risk of urinary retention. Postoperative pain following HIFU is generally mild. Because of this, patients' analgesic requirements are usually fulfilled with simple oral analgesics.

## HIFU in focal therapy

Initially, focal HIFU was not truly focal, but subtotal. For example, in 2008 Muto et al. published a series of men who underwent a bilateral peripheral zone as well as a unilateral transition zone ablation following a diagnosis of localized disease after template biopsy [33]. Of this group, postoperative biopsy was performed at 6 and 12 months, revealing residual disease in 10.7% and 23.5% of men respectively [33]. Following this there was a clear move to treat in a truly focal manner and in 2009 Ahmed et al. published the first series in which men with low- to intermediate-risk prostate cancer were treated with HIFU hemi-ablation [34]. Prior to being treated, each patient underwent a full assessment with mpMRI and template biopsy [34]. Transperineal biopsies were performed at 12 months following the procedure and these demonstrated residual disease in 11% of cases [34].

Since then, further case series have been published that demonstrate the efficacy of focal HIFU in treating localized prostate cancer [33–44] (Table 135.1). Centers using the Ablatherm device have reported 5-year biochemical survival rates (according to the Phoenix criteria) of 59–77% [35–37]. Similarly, series that use the Sonablate system have demonstrated 5-year biochemical survival rates of 45–84% [33, 38–41].

Postoperative negative biopsies are a good indicator of treatment success. Success rates according to this parameter vary by study in their timing and technique, but range from 64% to as high as 94% in those where the Ablatherm device is used [10, 35, 37, 42–44]. Similarly, studies in which the Sonablate system is used typically demonstrate 12-month postoperative negative biopsy rates of between 77% and 84% [33, 38, 40]. Retreatment rates are reported in the literature. An exact retreatment rate is difficult to quantify at present due to confounding by studies in which men underwent a second treatment as planned. However, current consensus is that a retreatment rate of 20% within the first 5 years of the primary treatment is acceptable [10].

Negative postoperative biopsies combined with low postoperative PSA nadirs represent the best results and these have been achieved most commonly in men with low-grade disease [36]. Such results compare well with external beam radiotherapy [45], although long-term results are currently lacking and thus optimism must be somewhat restrained. Moreover, the question of what constitutes or defines biochemical failure in men who have undergone HIFU remains essentially unanswered. This is partially due to the inherent difficulty in estimating the ideal posttreatment PSA nadir following any focal treatment for prostate cancer.

## HIFU in salvage therapy

Men with prostate cancer treated in the first instance with external beam radiotherapy or brachytherapy are at varying risk of recurrent disease in the long term, depending on the disease profile at diagnosis. For example, in men with intermediate- to high-risk cancer, the risk of biochemical recurrence can be over 50% after 10 years of follow-up [46]. These patients represent a cohort of men who are at high risk of disease progression to metastatic disease and, inevitably, death [47]. Of this group, up to 98% will receive systemic androgen-deprivation therapy (ADT) as part of their treatment of radio-recurrence, as well as the myriad of unpleasant side-effects that they carry [48]. Many of these patients, however, have solely organ-confined disease at the time of a diagnosis of radio-recurrence. These patients are suitable for focal salvage therapy, which has potential to prevent the need for ADT and its side-effects [49, 50].

Traditionally, salvage therapy is conducted in a whole-gland manner. However, regardless of the technique, this confers a substantial risk of urinary and sexual side-effects [49, 50] due to the previous radiation the region has been exposed to. We now know from histopathological studies that the site of recurrence often arises from the location of the index lesion that preceded treatment [51, 52]. Thus, a focal rather than whole-gland approach, which, similar to primary focal treatment, aims to treat only an area of diseased tissue, may offer cancer control while significantly reducing the risk of complications and side-effects of salvage treatment. Indeed, a systematic review of focal salvage treatment found the complication rates to be either comparable or favorable [53]. Focal HIFU is currently used in this role, albeit mainly in the context of clinical trials.

The first such series was published by Ahmed et al. in 2012 [54]. Thirty-nine men were treated for localized radiorecurrent disease with focal salvage HIFU, 23 with quadrant ablation and 16 with hemi-ablation. PSA responses were observed in 87% of the patient group and in 44% it fell to a nadir of less than 0.5 ng/ml [54]. In the men in whom a PSA response was observed there was a

63% rate of biochemical survival at 3 years according to the Phoenix criteria [54]. Furthermore, in the men where no such PSA response was observed, the rate of biochemical survival at 3 years was 0% by the same criteria [54]. Unfortunately, two patients developed metastases ultimately requiring ADT [54].

The largest yet series of focal HIFU for radiorecurrent disease was published by Baco et al. in 2014 [55]. This two-center study enrolled 48 patients between 2009 and 2012 with a median follow-up of 16.3 months [55]. The mean PSA nadir was 0.69 ng/ml [55]. During follow-up, recurrence was observed in the untreated lobe in 4 of the group and bilaterally in a further 4 [55]. The biochemical survival according to the Phoenix criteria was 83% at 12 months and 52% at 24 months [55]. Six men developed radiologically proven metastatic disease and in 2 further men PSA levels continued to rise in the absence of radiological evidence of metastases [55].

The concept of focal salvage therapy is clearly interesting and adding further options other than ADT to our armory is of extreme importance. However, further investigation is required in this area. It is especially important to determine whether this treatment improves long-term survival when compared to watchful waiting and subsequent systemic therapy. Such studies are currently in progress.

## Postoperative follow-up

Currently, no consensus regarding a defined follow-up protocol exists. However, a suitable regime is three monthly visits for the first postoperative year, six monthly visits for the second postoperative year, and yearly visits thereafter. At these visits PSA monitoring should be performed, as well as lower urinary tract and sexual function, as measured by the International Prostate Symptom Score (IPSS) and quality-of-life questionnaire, and the International Index of Erectile Function 5 (IIEF-5) questionnaire, respectively. Of note, PSA values should be interpreted with caution early after treatment as it may take several months before it reaches its nadir. Furthermore, an optimal definition of biochemical failure following HIFU is lacking. Until the recent past, many centers commonly used the old American Society for Therapeutic Radiology and Oncology (ASTRO) criteria of three consecutive rises in PSA to define biochemical recurrence. However, as this was designed specifically for biochemical recurrence 5 years following radical radiotherapy its use here is not validated and questionable [56]. More recently, however, the Phoenix criteria have been more widely adopted due to the increased robustness in artifact reduction.

Multiparametric MRI is an essential part of post-HIFU follow-up and is usually required 12 months postoperatively (Figure 135.9). Dynamic contrast enhancement (DCE) MRI is of particular use in determining whether there has been adequate early cancer control. A lack of enhancement demonstrates clearly the presence of necrosis and there is good correlation with biochemical outcomes [57]. Posttreatment targeted biopsy of the treatment area is often performed. The best time for this is 12 months postoperatively following the initial posttreatment mpMRI. However, this may be brought forward if there is cause to be concerned [10].

## Complications

The potential complications and side-effect profile of HIFU are well documented. Common side-effects are fairly benign and include visible debris in the urine, new or worsening of existing lower urinary tract symptoms, dysuria, and acute retention of urine. However, these are inconsistently reported in the literature. As demonstrated in Table 135.1, the rate of postoperative retention of urine is reported at between 0% and 6%. Urinary tract infections and cases of epididymo-orchitis occur in between 5% and 10% of patients [33–44]. Hematuria and hematospermia may be present and may persist for some time. In particular, hematospermia may persist for up to 8 weeks. Retrograde ejaculation is common in around 50% and between 0.5% and 15.4% of men [33–44] will develop urinary incontinence requiring pads. Carrying a risk of 5%, a less common side-effect is the development of a urethral stricture (Table 135.1). In comparison to the radical treatments, erectile dysfunction is generally a less common complication. Existing case series demonstrate impotency rates of between 13% and 53% [33–44]. However, the degree of potency in these series is often inadequately assessed and as such directly comparing their results is problematic. The most serious potential complication of HIFU is the recto-urethral fistula that occurs in between 1 in 500 cases [33–44]. In reality, the rate of this complication is likely to be lower as most of these recorded cases are in earlier series with prototype devices. Finally, there is an acceptable retreatment rate of 20% [10] within 5 years of treatment. Subsequent radical therapy is regarded as a true failure of treatment [10].

## Conclusion

HIFU may be considered as a potential minimally invasive treatment for patients with localized low- to intermediate-risk prostate cancer. More favorable oncological outcomes are seen in patients with lower preoperative PSA levels and lower Gleason grades on biopsy. The technique can also be used for salvage treatment, for example in case of radio-recurrence following radical external beam radiotherapy. However, HIFU should be offered with some caution and patients should be carefully selected according to both premorbid and prognostic factors. HIFU is still in relative infancy and as with any novel therapy its efficacy should be evaluated further, particularly in the context of long-term oncological outcomes compared to established radical treatment options. Such studies are currently ongoing and in combination with further technological advances, we are optimistic that the role of HIFU in localized prostate cancer will continue to expand.

## Introduction

Human experience has definitively established that cold temperatures kill living tissues. Certainly, arctic explorers and polar bear swim clubs have learned about the manifestations of frostbite as frozen cells become ischemic from exposure to freezing temperatures. The medical applications of such low-temperature exposure was first developed for the management of malignancy in nineteenth-century England. Modern technology has provided a mechanism to percutaneously target and ablate clinically localized prostate cancer using the same lethal cold temperatures delivered with needle probes cooled by high-pressure gas-based systems. This chapter provides information about the basic principles of cryobiology, current indications for cryotherapy of the prostate, and procedural details, and summarizes the outcomes as reported in the literature.

## Cryobiology: general principles

### Cryogenic injury

All living cells possess mechanisms for managing exposure to cold temperatures. The limitation of fluid flow across cell membranes, the high concentration of solutes in the cytoplasm and various proteins can minimize the mechanical effect of low temperatures and freezing of water. However, these mechanisms can be ultimately abrogated as the ambient temperature falls below a value of approximately −10 °C. As tissue is exposed to lethally cold temperatures the cells are destroyed through one of several mechanisms. These mechanisms can be summarized into two categories: direct cellular injury and vascular cryogenic injury [1].

Direct cellular injury has been extensively studied in cell culture models and is based on the physics of water and ice formation within the frozen tissue. Two separate mechanisms of ice formation have been described. Initially, ice forms in the extracellular space and propagates through the tissue as temperatures decrease. Since only free water will freeze, the solute concentration rises in the extracellular fluid that has not yet frozen. Intracellular water moves out of the cells in response to this change in osmolarity, causing cellular dehydration with a corresponding increase in the concentration of intracellular solutes. This change disrupts protein function and enzymatic activity and can result in apoptotic cell death [2, 3]. This may be called a solution effect injury.

The next direct injury is a result of the development of intracellular ice crystal formation that only develops at very low temperatures (estimated to be below −40 °C). It is also likely that rapid rates of freezing are required to cause freezing of water that is entrapped within the cells before dehydration has occurred. Intracellular ice formation alters cell physiology by disrupting cell membranes and contributes to cell death by direct cryogenic injury. These cells then die through the mechanism of necrosis or direct disruption rather than the programmed cell death described above. Increasing the duration of exposure to lethal temperatures (<−40 °C) may enhance cell destruction since the limited amount of water that remains unfrozen at the periphery may also freeze [4].

Additional cellular damage is created as the tissue is allowed to warm following the initial freeze process. During thawing, recrystallization occurs when the temperature rises above −40 °C. In the recrystallization process smaller ice crystals coalesce into larger structures that can further disrupt cellular membranes and fracture the cells. Moreover, as extracellular ice crystals melt, a hypotonic extracellular environment is created such that

*Smith's Textbook of Endourology*, Fourth Edition. Edited by Arthur D. Smith, Glenn M. Preminger, Louis R. Kavoussi, and Gopal H. Badlani.
© 2019 John Wiley & Sons Ltd. Published 2019 by John Wiley & Sons Ltd.
Companion website: www.wiley.com/go/smith/textbookofendourology

free water now flows back into cells, causing cellular edema, swelling, and injury. It has been suggested that passive thawing may be more efficient in prostate cancer destruction.

The second category of cryogenic injury is the vascular mechanism. This type of cryogenic injury occurs preferentially in the microcirculation. Vascular endothelial cells are more sensitive to cold-based injury (as generally understood from experience with frostbite injuries to the extremities of cold weather explorers) and slough into the vessel lumen, resulting in increased vessel permeability and platelet aggregation with thrombosis. This results in tissue ischemia, inflammation, and cell death through necrosis [5]. In addition, thawing and reperfusion injury mediated by the release of free radicals augments the endothelial cell damage and can enhance the inflammatory process with enzymatic degradation of the cellular debris.

Cryogenic injury progresses as the temperature drops and is a time-dependent process. Although cell dehydration occurs at temperatures between 0 °C and −20 °C this is insufficient to produce permanent cellular injury and death. Intracellular ice begins to form at temperatures below −20 °C and is maximal at temperatures below −60 °C, which is uniformly lethal for cancer cells [6]. Importantly, tissue at the periphery of the freeze zone may be exposed to less cold temperatures, despite being included in the frozen tissue, and receive only sublethal injury. In this zone of damage cellular apoptosis is the primary mechanism for cell death and is not uniform. Cryobiologists have attempted to augment the cellular injury that results from exposure of cells to sublethal temperatures in an effort to increase the percentage of cancer cells that suffer programmed cell death. Clarke et al. have demonstrated that several different chemotherapeutic agents can potentiate the lethal impact of freezing cancer cells and may represent the optimal mechanism for destroying all cells within a target tissue volume [7].

### Cryoimmunology

The mechanical freeze fracturing of living cancer cells has been demonstrated to release tumor antigens into the microcirculation and initiate an immune response [8, 9]. This potential therapeutic mechanism has been demonstrated in rats treated with cryoablation of a prostate cancer with concomitant administration of BCG [10]. Despite these results, the clinical exploitation of this phenomenon has been limited, although recent studies have suggested that the immune response to the cryoablation of a malignancy within the prostate can be augmented with systemic agents [11, 12]. It remains possible that a multimodality approach using local cancer cryoablation with systemic immune modifiers may result in the treatment of metastatic prostatic cancer in the future.

## Indications for cryotherapy of the prostate

Primary cryoablation of the prostate is considered to be an option for the treatment of localized prostate cancer. The American Urologic Association's (AUA) Best Practice Statement considered cryosurgery to be an option for patients who either do not desire or are not good candidates for conventional treatment modalities [13]. The European Association of Urology considers cryoablation of the prostate to be investigational at this time [14].

The optimal candidates for primary cryoablation of the prostate for curative intent are men with likely organ-confined prostatic malignancy with prostate gland volumes between 25 and 80 ml without significant protrusion of the prostate into the bladder or the rectum. The AUA Best Practice Statement indicates that cryoablation is an option for low-, intermediate-, and high-risk clinically localized prostate cancer, setting no apparent limits to prostate specific antigen (PSA) values, clinical stage, or biopsy Gleason score. However, this document does not specifically address the suitability for cryosurgery of high-risk patients who may require multimodality treatment. It is likely that the optimal clinical stage for prostate cryoablation is cT1 or cT2 tumors. Cryoablation has been evaluated in men with clinical T3 cancers with mixed results [15, 16]. Therefore men with locally advanced prostatic cancers may elect for cryoablation but with the understanding that the risk of incomplete ablation and of associated toxicity is increased.

Prostate cryoablation has demonstrated the capability to destroy prostatic tissue with a reduction in the volume of the prostate gland following the procedure, suggesting that this modality can treat men with clinically localized prostate cancer and associated benign prostatic enlargement with voiding dysfunction [17]. Therefore, men with prostate cancer within the setting of benign prostatic enlargement may elect this treatment approach rather than alternatives that do not reduce the volume of prostatic tissue.

### Salvage cryoablation

Salvage prostatic cryosurgery after primary radiation therapy has been proposed as an alternative to salvage radical prostatectomy with the potential for reduced morbidity. Salvage cryoablation has been reported after interstitial brachytherapy as well as external beam therapy [18]. There have been no prospective comparison trials between salvage radical prostatectomy and cryoablation following initial radiation therapy but clinical case series have suggested that the surgically related toxicity is likely reduced with cryoablation [17]. In addition, the oncologic outcome of cryoablation in the salvage setting may be related to the location and volume of persistent malignancy within the prostate gland [19].

Therefore, candidates for salvage prostate cryoablation include men with a small volume of prostatic cancer, as identified on postradiation prostate biopsy, following evaluation for an elevated PSA following first-line therapy without radiographic evidence of metastatic disease. The optimal PSA level for salvage cryoablation has not been established but is likely similar to that of a salvage radical prostatectomy. A serum PSA value below 4 ng/ml has been associated with the highest likelihood of organ-confined prostate cancer that can be eradicated with a radical prostatectomy. It is possible that this value is similar for salvage cryoablation [20].

Radiation-persistent prostatic adenocarcinoma is associated with a higher incidence of seminal vesicle invasion and higher pathologic Gleason sum on prostate biopsy [21]. Although cryoablation is capable of destroying the malignancy irrespective of the histologic grade, successful management of invasive disease within the seminal vesicles is unlikely. Therefore, a seminal vesicle biopsy could be helpful in determining the correct candidate for a salvage cryoablation.

## Cryoablation procedure: whole-gland therapy

As technology has improved over the years, we discuss only the current third-generation technology, leaving the description of previous techniques (first and second generations) to historical reference.

Third-generation cryotechnology is based on dual-gas systems exploiting the Joule–Thomson principle of gas expansion to provide heat subtraction and delivery through small-caliber cryoprobes. The same effect is used in home appliances such as air conditioning systems and refrigerators. Briefly, these systems use pressurized argon and helium gases delivered to the cryoprobe in a closed circuit. When argon gas is allowed to expand through a pinhole opening at the tip of the cryoprobe, the gas changes its internal energy state as the pressure drops and the process consumes energy, thereby reducing the temperature. The inverse process happens during thawing, whereby helium is expanded in the cryoprobe, thus releasing energy and heating the probe. The opposite effects achieved with the two gases derive from different molecular properties (internal energy) of argon and helium gases, based on attractive and repulsive forces of gas molecules. The latest technology introduced an argon-only system whereby both freezing and thawing phases are achieved by altering the physical properties of argon, thus simplifying the technologic complexity of cryoablation and obviating the need for an additional gas.

The cryoablation suite consists of a console that monitors and controls the procedure, argon (and sometimes helium) pressurized gas tanks, a urethral warming device, and peripherals (transrectal stepper-mounted ultrasound, cryoprobes, and thermocouples). The system's user interface integrates ultrasonographic imaging that guides cryoprobe positioning and monitors the formation of the iceball, receiving input from the urethral warmer and the temperature probes.

Different numbers, positions and configurations of probes allow for sculpturing of the iceball with precision. Cryoprobes and thermocouples are positioned transperineally through a brachytherapy-like template (Figure 136.1). Currently, thin and ultrathin (17G, 1.5 mm) cryoprobes are available. Iceball formation is monitored both by temperature probe readings and by real-time ultrasound.

Cryoablation is typically an outpatient procedure and can be performed under general, spinal, or locoregional anesthesia. With the patient in lithotomy position, probes are positioned using the grid under the guidance of transrectal ultrasound. Thermocouples are typically positioned adjacent to the neurovascular bundles, sphincter, and Denonvilliers' fascia to assist with iceball monitoring. After probe positioning, flexible cystoscopy is used to verify that the probes have not penetrated the urethra or bladder. The urethral warming device is then introduced

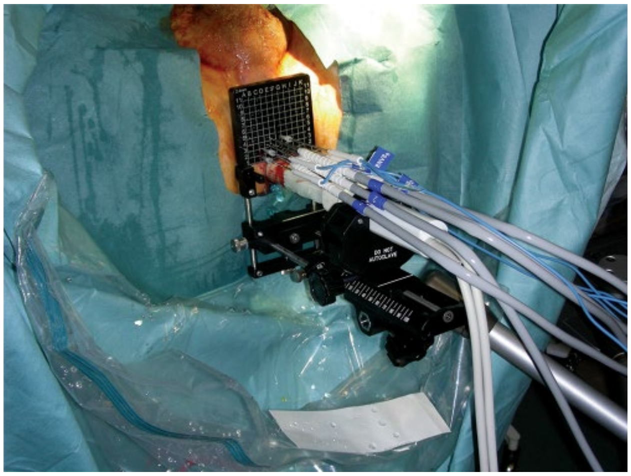

**Figure 136.1** Transperineal percutaneous prostate cryoablation under ultrasound guidance. Prostate cryoprobes are placed percutaneously into the prostate through a brachytherapy grid under ultrasound guidance.

over a super-stiff guidewire. Although some surgeons place a suprapubic tube to provide bladder drainage in the postoperative period, a urethral catheter can alternatively be utilized at the end of cryoablation, replacing the urethral warming device. Freezing proceeds in an automated manner, using dual freeze–thaw cycles, monitored by ultrasound and thermocouple readings.

Cryoablation results in acute swelling of the prostate that typically resolves in 1–2 weeks, during which time a urethral catheter (or a suprapubic tube) provides bladder drainage. After a successful voiding trial, the catheter can be removed. We recommend assessing voiding ability within one week postoperatively as in our experience most patients are able to spontaneously void by that time.

## Outcomes

### Oncologic outcomes of primary whole-gland ablation

The oncologic outcomes of primary prostate cryoablation have been extensively evaluated in both single-institution and pooled population studies and are presented in Tables 136.1 and 136.2. The reported clinical series suggest that cryoablation of the prostate can achieve acceptable long-term disease-free survival rates that are comparable to alternative options such as radical prostatectomy and radiation therapy. However, there have been no prospective trials that can provide more definitive information about the cancer control rates for cryoablation relative to these more established therapies. In addition, the definition of a successful ablation is variable and no specific PSA value has been established as a clear indicator for disease eradication. A pooled analysis of 1111 men demonstrated that 80% achieved a postcryoablation PSA nadir below 0.4 ng/ml. This achievement was then associated with a 90.4% progression-free survival for low-risk men, 81% for intermediate-risk and 73.6% for men with high-risk malignancy at 5 years [22]. Another pooled analysis demonstrated similar findings, with 14% of men having persistent cancer on a routine postcryoablation prostate biopsy [23]. Finally, cryoablation resulted in a 59.1% biochemical progression-free survival at 5 years following therapy in men with high Gleason score prostatic cancer, suggesting that this modality is a rational option for some men with high-risk disease [24].

### Oncologic outcomes of salvage prostate cryoablation

Pisters et al. reviewed the oncologic outcomes of 279 men treated with salvage prostate cryoablation after primary radiation therapy and found that 83% of men manifest detectable PSA levels but with a 58.9% biochemical recurrence-free survival at 5 years following treatment [20]. Since transperineal percutaneous prostate cryoablation is a very flexible treatment approach which can be alerted to individualize therapy for men based on cancer location, prostate anatomy and desire to reduce specific treatment-related side-effects it is possible to reduce the volume of the prostate tissue included in the ablation zone even in the salvage setting. A series of 91 men were treated with such a reduced ablation template, described as a focal ablation, for salvage therapy and achieved a 46.5% biochemical recurrence-free survival at 5 years [25]. These results suggest that the oncologic outcomes of salvage cryoablation are acceptable given the complexity of this patient population.

**Table 136.1** Oncologic outcomes of primary cryoablation.

## Complications of whole-gland primary cryoablation

Percutaneous transperineal prostate cryoablation is performed under transrectal ultrasound guidance and was developed to specifically avoid some of the side-effects related to radical prostatectomy and radiation therapy options. In fact, it is the hope for a reduction in overall toxicity that makes cryoablation an attractive option for men with clinically localized prostatic adenocarcinoma. However, there are several associated side-effects from cryoablation that should be exposed to the patient during the informed consent discussion.

Minor self-limiting complications include transient scrotal edema, penile edema with ecchymosis, and possible penile paresthesia [35]. These symptoms typically develop immediately following the procedure and resolve within 2–3 weeks. Table 136.3 gives a summary of the complications after primary whole-gland cryoablation.

Urethral mucosal sloughing is rare and in most series is reported to occur in less than 5% of patients. The incidence of rectourethral fistula today is also low (0–2.4%). Urinary incontinence requiring pads has been reported to occur in less than 10% of patients and is typically transient. The incidence and presentation of incontinence has been reported using various definitions, with most studies not distinguishing between stress, urge, and mixed incontinence, making it challenging to derive precise conclusions. The incidence of urinary retention has varied widely across the literature and requires further evaluation as technical differences may have accounted for this discrepancy between studies. However, the majority of urinary retention events are transitory and resolve within 2–4 months. The more recent series suggest urinary retention may occur in less than 5% of cases [25, 35].

A recent report based on the CaPSURE database analyzed the incidence of urethral stricture after primary therapy for prostate cancer. The overall incidence of stricture after primary cryosurgery was 2.5%. At 1, 2, and 4 years, 96%, 95%, and 87%, respectively, of cryotherapy patients were stricture free. These data compare favorably to other treatment options: incidence of stricture formation 1.1% for watchful waiting, 2% for androgen-deprivation therapy 2%, and 8.4% for radical prostatectomy.

Currently, the available data are limited both due to many of the reported series being updates of previous studies and because data collection has not been standardized, thus precluding a detailed and accurate description of complications after cryoablation. Researchers should strive to better collect follow-up information to delineate accurately the complications profile and determine risk factors for these adverse events.

## Complications of whole-gland salvage cryoablation

A summary of complications after salvage cryoablation is outlined in Table 136.4. Overall, the toxicity profile appears similar to that of primary cryoablation with the exception of increased rates of urinary incontinence and pelvic pain. Overall, salvage cryoablation offers a complication profile that compares well with other salvage techniques. A recent review of the literature concluded that salvage cryoablation represents a viable alternative to the technically challenging salvage radical prostatectomy and can be recognized as an established option for radiopersistent or recurrent prostate cancer [41].

## Functional outcomes: urinary continence and erectile function

Information about urinary incontinence and erectile dysfunction following whole-gland primary and salvage prostate cryoablation are given in Tables 136.3 and 136.4. Erectile dysfunction is highly prevalent after whole-gland therapy and should be expected in the salvage setting. Importantly, although erectile dysfunction in previously potent men would be universal in the immediate postoperative period, with whole-gland primary cryoablation longer term follow-up suggests that as many as 46.8% of men will regain erectile function by 24 months [43]. This recovery was confirmed in a prospective trial comparing cryoablation to high-frequency ultrasound ablation [44]. Therefore, the changes to erectile function should be discussed with men prior to the selection of this treatment approach; many men with normal preoperative erectile function can expect recovery of this state over time.

The accurate placement of cryoprobes into the prostate through a brachytherapy grid under transrectal ultrasound guidance allows for the development of an individualized ablation template that can minimize injury to the pelvic floor and urethral sphincter. In fact, this technical possibility is one of the more attractive aspects of this surgical approach for many men with clinically localized prostate cancer. The manufacturers of cryoablation equipment have developed cryoprobes with short iceball lengths or even adjustable iceball lengths that allow for the targeted ablation of prostatic tissue while reducing the risk of injury to the sphincter.

[a] Series includes a portion of cases treated using second-generation technology.

UTI, urinary tract infection; ED, erectile dysfunction, NR, not reported.

Urinary continence rates are as high as 98% at 24 months following whole-gland ablation [43, 45].

## Future modifications of prostatic cryoablation: focal or individualized therapy

The incorporation of transrectal ultrasound guidance into the performance of transperineal prostate cryoablation has provided an opportunity to more fully understand the individual patient's prostate anatomy as well as the location of the known prostatic cancer. In addition, retrospective evaluations of whole mounted prostate specimens from radical prostatectomy series have identified the most likely location and volume of all lesions within the prostate of men with clinically localized adenocarcinoma [46]. Therefore, the technical flexibility of the ablation approach coupled with improved information about cancer volume and anatomic location should allow a more precise destruction of the malignancy while avoiding injury to adjacent structures. This concept of a targeted ablation has become known as an individualized ablation, or more commonly, focal ablation. Figure 136.2 depicts one such ablation template with a focus on a left side cancer within the prostate.

Prostatic adenocarcinoma has been established as a multifocal disease process within the prostate gland of aging men. However, early detection strategies have resulted in the identification of prostate cancer with a smaller volume of malignancy and a reduced number of satellite lesions [47]. Onik and co-workers provided the first report of a focal ablation, defined as a less than total ablation of the prostate directed at the known malignancy, in 2002. They documented effective reduction in the postoperative PSA with negative follow-up prostate biopsy in a total of nine men associated with retained urinary control and erectile function [48]. The authors advocated for the term “male lumpectomy” to describe this technical approach [49].

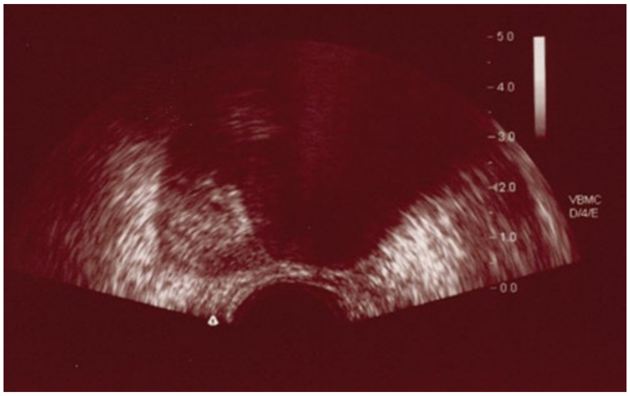

**Figure 136.2** Focal prostate cryoablation. A less than total focal prostate cryoablation is performed for a left side prostatic adenocarcinoma designed to avoid injury to the right side neurovascular bundle.

Since that publication a number of other investigators have pursued focal ablation as a viable treatment option to maintain oncologic efficacy while reducing treatment-related intensity and toxicity. A pooled analysis in 2012 identified 1160 men who had been treated with a focal ablation [50]. Approximately 3.7% of these men were found to have persistent prostate cancer on follow-up biopsy, suggesting that a less than total ablation of the prostate has only a small risk for incomplete disease eradication in properly selected men. It also appears that there

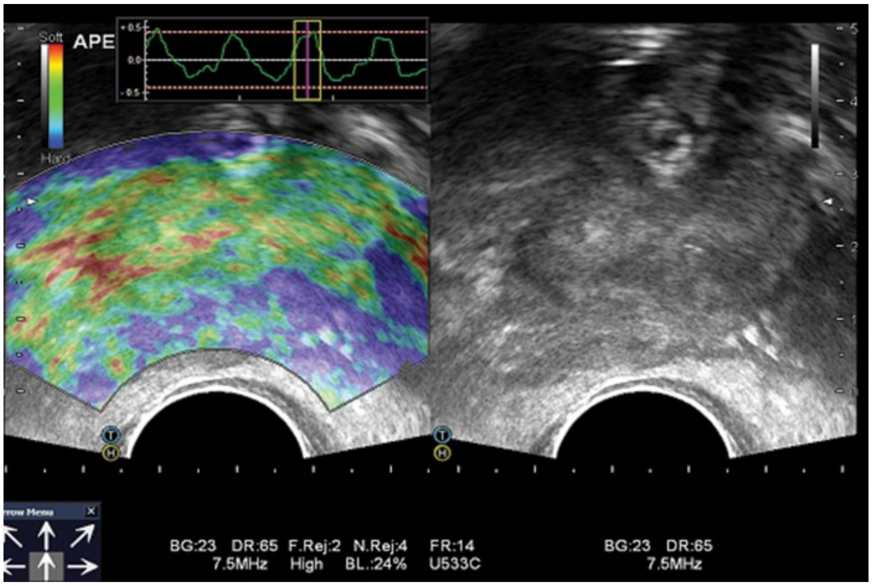

**Figure 136.3** Elastography for prostate cancer. Transrectal ultrasound of the prostate with strain elastography identifying a region of increased stiffness (blue) in the left lateral base.

is a reduced risk of urinary incontinence as well as a high rate of return of satisfactory erectile function [51, 52].

Focal or individualized prostate cryoablation designed to eradicate the known cancer while avoiding injury to the adjacent neurovascular bundles and pelvic floor represents an attractive technical advance in the management of clinically localized prostate cancer. It is possible that this treatment will improve further as new imaging modalities such as multiparametric prostate MRI and multiparametric prostate ultrasound using Doppler and elastography (depicted in Figure 136.3) provide improved localization of the prostatic cancers within the prostate gland [53, 54].

# Cryosurgical Ablation of the Prostate

*Rajan Ramanathan, Yaw A. Nyame, & J. Stephen Jones*

*Department of Urology, Glickman Urological and Kidney Institute, Cleveland Clinic, Cleveland, OH, USA*

## Introduction

Cryosurgery involves the use of ultra-low temperatures, below the freezing point of water, which causes thermal tissue damage and cell death. Cryoablation of the prostate is a minimally invasive treatment option for prostate cancer that offers shorter hospital stays, minimal risks of bleeding, and can even be offered to patients who are not good surgical candidates.

In 2004 almost 25% of patients underwent minimally invasive primary treatment of prostate cancer and of these 2.8% underwent cryoablation [1]. In 2010 this number had risen to 4% [2], and from the Cryo-On-Line Database (COLD) registry data we note that over 50% of patients who underwent cryoablation did so as a primary treatment modality for prostate cancer.

## History of cryoablation

Cryoablation actively uses the Joule–Thomson effect. When a compressed gas undergoes sudden expansion it causes a change in temperature. Many gases cause a cooling effect, but helium causes warming (Figure 137.1). This physical effect of cooling during cryoablation was first achieved using nitrogen and then, later, argon. With the demonstration that freeze–thaw cycles cause a more sustained and predictable cell death, the newer generation machines for ablation started using argon–helium combination. From when prostate cryoablation was first described in the 1960s, the technology and technique have undergone a process of steady evolution.

One of the earliest descriptions of cryosurgery involved the use of salt solutions to achieve subzero temperatures in order to induce tissue destruction in easily accessible cancers like those of the breast and uterine cervix. Subsequently cotton swabs soaked in liquid nitrogen were described for the treatment of skin lesions [3].

In 1961, Cooper and Lee first described the use of a hollow cannula constructed of stainless steel with an outer and inner tube. The length of the cannula was electrically insulated using copper wire and this was kept at body temperature, but the tip itself was noninsulated and was used for delivery of iceball measuring 8 mm in size in their experiments [4].

Prostate cryosurgery was first described by Gonder et al. in the 1960s [5, 6], and since then many technical refinements have continued to occur. The third-generation devices now use the argon–helium gas combination to produce the freeze–thaw cycles. Ablation probes have also decreased in size, and fine 17 gauge cryoprobes can now deliver precise iceballs measuring 8–10 mm in diameter.

The use of transrectal ultrasound (TRUS) to monitor the "cryolesion" or iceball was developed and popularized by Onik et al. in 1988 [7], and subsequently the same group described the use of a urethral warming device in 1993 to protect the urethra against injury [8].

Techniques aimed at improving the efficiency of cryoablation while minimizing complication rates followed. Onik et al. reported that raising the TRUS probe to push on the posterior wall of the rectum caused the anterior rectal wall to be pulled away from the prostate, creating a spatial separation between the prostate and the rectum [8]. Onik later described another technique to further accentuate this separation by injecting saline into the layers of the Denonvilliers' fascia [9] to minimize the chances of a rectal injury and rectourethral fistula. They also showed that the use of 6–8 cryoprobes results in better prostate tissue destruction than the original five-probe technique [9].

Prostate cryoablation devices are now into the third generation. The first-generation devices used liquid nitrogen and the probes were larger. The total time required for the procedure was also longer and

temperature monitoring was not possible. The machines were also bigger and lacked mobility (Figure 137.2). The second-generation machines were more compact, and used freeze–thaw cycles with helium gas for the thaw cycles. The third-generation machines incorporated the technology into ultrathin 17G probes, along with temperature monitoring (Figure 137.2).

## Mechanism of tissue injury and cell death in cryoablation

Cryoablation causes cell damage through a drop in temperature that causes freezing. The aim of cryoablation is to cause destruction of the tumor by creating overlapping cryoablation zones to encompass the entire volume of tumor, while minimizing collateral damage to surrounding normal tissues. Various studies have looked at the minimum temperature required to achieve destruction of tumors, and the mechanisms of injury, importance of cooling rates, and time of contact, as well as the effect of freeze–thaw cycles.

In their review, Cooper summarized five mechanisms that are responsible for tissue destruction: dehydration and change in electrolyte concentration due to removal of water from solution, crystallization with rupture of cellular membranes, permanent change in the protein molecules of the cell membrane causing irreversible loss of semi-permeability, thermal shock, and vascular stasis and coagulation [10].

Today we understand the importance of intracellular ice formation which causes the secondary osmotic shifts from structural damage to the semipermeable membrane. This has been postulated to be an important mechanism of cellular rupture and death in cells in contact with, or very near to the cryoprobe and its iceball. However, there is a rise in temperature more peripherally and in this zone other mitochondrial and cytokine-mediated cellular injury occurs [11]. Studies have shown that Bax, a cytoplasmic protein that promotes apoptosis, is increased in the cytoplasm on thawing, [11], but it is the ratio of the Bax to the Bcl-2 (a mitochondrial membrane antiapoptotic protein) that determines whether a cell can survive the effect of marginal freezing that does not cause direct cell rupture [12].

Robilotto and colleagues have performed *in vitro* studies describing possible apoptotic pathways responsible for cell death using PC-3 prostate cancer cell lines and by analyzing caspase activity. Caspase-9 is considered a key component of the intrinsic pathway that follows release of mitochondrial proteins and cytochrome *c*, whereas caspase-8 is a marker of the Fas pathway death-induced signaling complex (DISC) [13]. Robilotto et al. showed that cell death started within 30 minutes of freezing to temperatures <−30°C, peaked at 90 minutes and was complete within 6 hours. Cell death in this model occurred predominantly through membrane-mediated pathways [13]. Apoptosis was more delayed in cells that were exposed to temperatures over −30°C occurring between 6 and 24 hours, and the mechanism was believed to be through an intrinsic or mitochondrial pathway [13].

Other *in vitro* cryoablation models have been conducted in the laboratory for the purpose of determining the causes of cell death and also to refine ablation techniques (i.e. to optimize the number of freeze–thaw cycles). Temperatures of −15°C to −20°C are achieved before ice crystals start to form [10]. However, Neel et al. showed that even −28°C is not uniformly lethal to tumor cells [14], and recommended repetitive freezing to temperatures below −60°C for effective tumor ablation [15]. Staren et al. studied the effect of cryoablation on breast tumors, and found that when the temperature at the periphery of tumors was maintained at −40°C for <7 minutes, there was good response in tumors <1.5 cm, but there was viable tumor cells at the periphery with larger tumors. When the temperature was further dropped to −70°C, there was still no significant difference in the outcomes even with the addition of a two-freeze, passive thaw cycle, until the freeze time was increased to 15 minutes [16].

A general consensus exists that temperatures of −40°C, have been shown to cause adequate cell destruction. The mechanism of cell death is different at different freezing rates: at rapid freeze rates of over 25°C per minute it is due to rapid intracellular ice formation, but at slower freeze rates of less than 5°C per minute, changes in the chemical composition of the cells were the main mechanism of cell death [17].

Since intracellular ice formation is an important component of cryoablation, it is essential to understand the factors that affect it: rate of cooling and the endpoint temperature can be controlled extrinsically, but the water content of tissues and the presence or absence of nearby heat sinks (such as major blood vessels that can transfer energy rapidly and prevent achievement of target temperatures) are intrinsic to the tissues being ablated. The cooling rate and endpoint temperature achieved are also interrelated. A more rapid cool rate of 25°C/minute can achieve cell death at higher temperatures of −19°C and the endpoint temperature does not need to go all the way down to −40°C [17].

Ice is a bad conductor of heat and, as more ice forms, it starts to prevent further propagation of the iceball. There are, therefore, limits to the size of the iceball that can be achieved for a given rate of cooling, and for cooling rates more than 25°C/minute, an iceball equilibrium is achieved at 8–10 mm in size [17].

Today's latest generation machine can achieve adequate intracellular ice formation through double or even triple freeze–thaw cycles [17, 18], and by ensuring the correct cooling rate for a given endpoint temperature.

## Types of cryoablation

The commonly used cryoblation techniques are shown in Figure 137.3. Targeted ablation is not often used since a conventional biopsy cannot detect all tumors. Targeted ablation is ablation of a well-defined lesion, proven on biopsy. The ablation aims to destroy the tumor and a part of surrounding normal prostate similar to the partial nephrectomy model. (Figure 137.3 left side of prostate) This form of ablation can have a good nerve-sparing effect, but the risk of recurrent or residual cancer is higher. Targeted ablation would be optimal for repeat or second ablations in patients who have had a primary ablation. Zonal ablation is a slightly more extended form of ablation that involves more prostate tissue and aims to encompass all areas with biopsy-proven cancer. In general, zonal ablation involves contiguous areas, but can be combined with targeted ablation of a single focal lesion too. Hemigland ablation (Figure 137.3 right side of the prostate) involves ablation of one lobe of the prostate and whole-gland ablation involves ablation of the whole prostate.

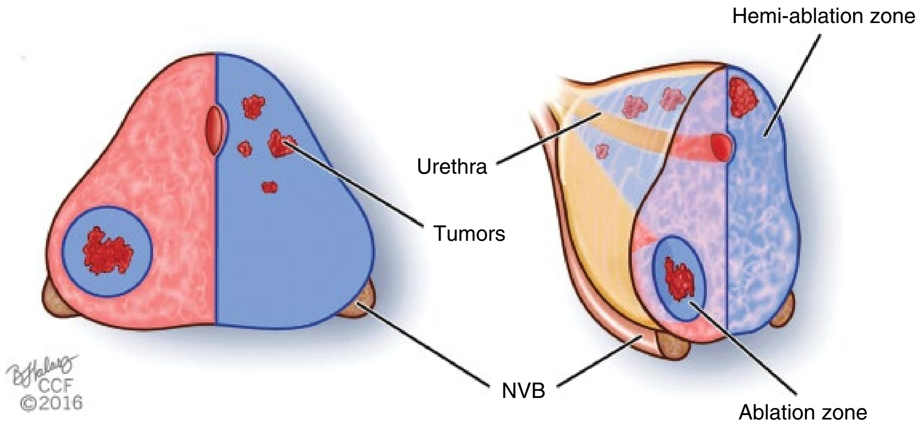

**Figure 137.3** Types of cryoablation: Targeted ablation on the left side of the prostate and hemiablation on the right.

## Patient selection

Prostate cryoablation is now being offered in the primary and salvage setting. Appropriate case selection is essential for ensuring optimal results, better biochemical relapse-free survival, and lower complication rates.

An ideal treatment model relies on the accurate and consistent identification of tumors in their entirety, and treatment delivery that consistently and predictably eliminates all of the cancer without causing any collateral damage to normal tissues. Cryoablation for prostate cancer does not consistently conform to the ideal treatment model. First, assessment of the anatomical extent of disease in terms of tumor location and volume cannot be accurately or consistently performed in all cases. Second, cryoablation, as a technology, has some limitations in how consistently and predictably it can eliminate prostate cancer without affecting the urethra, external sphincter, and neurovascular bundles. Lastly, there are challenges with following patients after nonexcisional treatment such as cryoablation, since we continue to rely on surrogate markers of recurrence used after radiation therapy.

Since the aim of treatment is to provide oncologic cure, while minimizing complications, it is extremely important to identify any parameters that are statistically associated with higher failure rates or with poorer clinical outcomes. In general, patients with high-volume or aggressive disease, such as extraprostatic extension or seminal vesicle involvement, will demonstrate poor clinical outcomes as a result of higher rates of residual disease and/or higher rates of complications.

On the other hand, patients without high-volume or high-risk disease are potential candidates for focal treatment, which has lower complication rates compared to whole-gland cryoablation. A study on salvage cryoablation showed higher rates of urinary incontinence (13% vs. 0%), erectile dysfunction (100% vs. 71%), and fistulas (4% vs. 0%) in patients undergoing total cryoablation as compared to focal ablation [19].

Prostate cancer is often multifocal, as found in 79.5% of whole-mount prostate specimens after radical prostatectomy [20]. Cancer proximity to the urethra is also another cause for concern since urethral warming devices, designed to prevent cryo-injury to the urethra can potentially result in undertreatment in select patients. Studies have shown that in up to 66% of cases, foci of cancer were found within 5 mm of the urethra [20] with a mean distance of 3 mm from the urethra (17% of them in contact with the urethra) [21]. The prostate apex is another area that is at risk for residual cancer after cryoablation, with some studies suggesting that up to 74% of patients have apical cancers [21].

Results from salvage prostatectomy series also reflect similar patterns, with multifocal cancers seen in 28% of men, apical recurrences in 95% of men, and 65% of cancers found to be within 5 mm from the urethra (7% involving the urethra) [22]. In fact, radiation-resistant cancers show high incidence of extraprostatic extension (43%) and seminal vesicle involvement (28–62.5%) [22, 23], and such patients are not suitable for cryoablation with curative intent.

Routine prostate biopsies often do not detect the extent or volume of prostate cancer, and studies have demonstrated multifocal bilateral disease in 70.7–72.0% of men diagnosed with unilateral cancer on biopsy after review of the final radical prostatectomy specimens [24, 25]. Moreover, extracapsular disease was seen in 5% of men who underwent prostatectomy, on the side deemed to have completely benign pathology at biopsy [24]. More extensive saturation biopsies, in theory, may appear to be able to improve detection rates. This may then improve concordance between biopsy and radical prostatectomy [26], but other studies have not confirmed this. True unilaterality was inaccurately noted in 90% of patients (35 of 39) and 1–3 prostate cancer foci were missed on the saturation biopsy, of which 76% were determined to be clinically significant [27].

Multiparametric magnetic resonance imaging (mpMRI) fusion biopsy is increasingly being used and is now a recommendation for the workup of patients undergoing focal therapy as part of clinical trials [28]. Siddiqui et al. showed that there is good concordance between mpMR fusion biopsy and standard biopsy (69%). More specifically, mpMRI-targeted fusion biopsy demonstrate a 30% improvement in the detection of significant cancer over standard 12-core biopsy, and a combination of mpMRI-targeted and standard template biopsy had an overall sensitivity of 85% for detecting prostate cancer [29]. However, mpMRI technology is relatively new, with a significant economic cost of adoption, and results will vary based on physician experience. In addition, some tumors are not visible on mpMRI, and technical errors such as patient movement or mismatches in registration and/or fusion can cause inadequate sampling of the target lesion [30].

Conventional prostate cancer staging such as computed tomography (CT) abdominal sectional imaging and bone scans are inaccurate at the lower PSA levels commonly seen in the group of patients undergoing focal therapy. Overall, MRI staging accuracies of 71–72% have been reported [31]. However, there are some useful findings that MRI can provide with regard to disease staging. For example, the presence of suspected T3 disease on MRI is highly correlative, with metastatic disease in nodes as small as 0.8–1 cm, the accuracy of which improves when combined with staging nomograms [32]. The rates of micrometastatic nodal disease can be predicted with high sensitivity (88.9–100%) and specificity (65–94.6%) in the presence of clinical T3 (a and b) disease on MRI [31].

The role of a routine pelvic lymph node dissection (PLND) for staging prior to cryoablation has not been established. PLND can be done either by the conventional open technique or by laparoscopic or robot-assisted laparoscopic techniques. For PLND to be useful, enough lymph nodes, have to be sampled. The rate of residual cancer is about 13% in patients who undergo standard PLND when compared to extended templates which includes the presacral nodes [33]. An open extended PLND does blunt the advantage that a minimally invasive procedure such as cryoablation has to offer in the first place. Advances in minimally invasive surgical techniques provide additional options to open PLND that may confer the added benefit of less pain, improved cosmesis, and less hospital days with acceptable oncologic outcomes, but many of these studies demonstrated the efficacy of the minimally invasive technique when offered concurrently with the prostatectomy [34]. At this time standard open PLND is associated with a yield of 21–23 nodes [35], and minimally invasive approaches to PLND may potentially understage patients as a result of lower node counts on resection [36].

Assessing occult bone metastases can also be challenging. When the PSA is <10 ng/ml, bone scans have not been shown to be useful. Positive bone scans are seen with increasing PSA levels, rising from 8% for PSA levels between 20 and 50 ng/ml to 40% for PSA >50 ng/ml [37]. Other modalities, including NaF positron emission tomography (PET)/CT using $^{18}$F-sodium fluoride [38], MRI–diffusion-weighted imaging (DWI) and $^{11}$C-choline PET/CT [39], and fluciclovine ($^{18}$F) PET scans [40], are demonstrating promise in improving the detection of bony and other visceral distant metastases.

## Primary cryoablation

Prostate cryoablation is now being offered to more patients in the primary setting. When the COLD registry was reviewed as of December 2015, over 5000 patients were noted to have undergone primary cryoablation (Figure 137.4). A consensus study involving experts in the field of focal therapy looked at selection criteria for patients. There was a high level of agreement that focal therapy should now be used more in National Comprehensive Cancer Network intermediate-risk patients, and this is a shift over time, from previous policies restricting treatment to the low-risk group, due to concerns about “overtreatment” in the low-risk group [41]. There are other studies showing the effectiveness of focal therapy in the intermediate-risk group. Bahn et al. studied focal ablation in a selected group of 73 patients: 48 underwent biopsies after hemigland ablation for low and intermediate disease. Although 12 biopsies were positive, only 1 was positive on the treated side [42]. In their matched-pair analysis with radical prostatectomy, patients fared comparably to surgery, and there was no

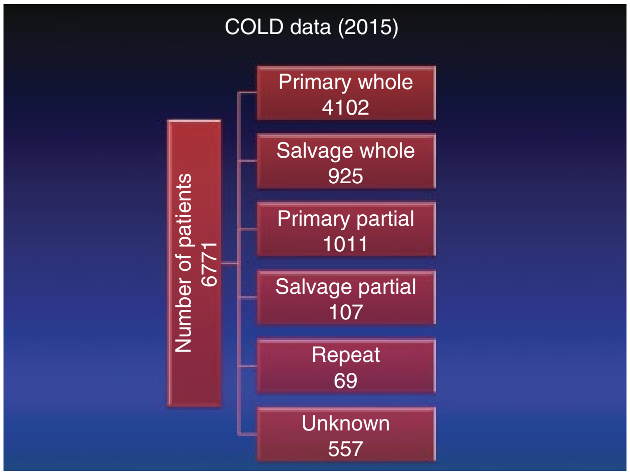

**Figure 137.4** Cryo-On-Line Database (COLD) data: Number of patients undergoing cryoablation as of December 2015 (data provided by Ahmed Elshafei).

statistical difference in the need for salvage treatment [42]. However, when there is evidence of locally advanced or clinical T3 cancer, a much higher rate of biochemical failure (48–52%) is noted compared to radical prostatectomy or radiation therapy [43, 44], with higher rates of rectourethral fistula [43].

Undiagnosed lymph node involvement (LNI) can occur and could be a cause of treatment failure. Accurately discerning the presence of LNI presents challenges to practitioners performing cryoablation, as positive nodes cannot be reliably identified by standard imaging modalities. For this reason, PLND is recommended for high-risk patients (i.e. those with higher PSA, higher grade disease, and shorter PSA doubling times).

Primary cryoablation should be offered to patients with acceptable risk criteria. Low-risk patients may be better followed on active surveillance and a recent study showed an actuarial cause-specific survival rate of 98.1% and 94.3% at the 10- and 15-year period, with 2.8% of patients developing metastatic disease [45]. Intermediate-risk patients with preexisting erectile dysfunction may be excellent candidates for cryoablation. Intermediate-risk patients with good preexisting sexual function should be aware that postprocedure sexual dysfunction is a possibility before proceeding with cryoablation. Although there are studies to demonstrate effectiveness of cryoablation for high-grade disease [43] routine use of cryoablation for patients with Gleason scores 8 or greater, tumor stage >T3, or those suspected of having LNI is not recommended.

### Salvage cryoablation

Similar criteria for patient selection applies to men undergoing salvage cryoablation after radiotherapy. The diagnosis of prostate cancer recurrence after radiotherapy needs to be confirmed and is aided by numerous imaging modalities, including MRI and confirmed by a biopsy. Pelvic MRI can utilize diffusion weighting and dynamic contrast enhancement to differentiate benign tissue from malignant disease. Magnetic resonance spectroscopy can be used to detect local prostate cancer recurrence [46]. In addition, mpMR has demonstrated increased accuracy in detecting prostate cancer in patients when compared to standard T2-weighted images, and consequently has significant utility in the detection of disease recurrence following radiotherapy [47]. These adjunctive imaging modalities can facilitate the selection of men for prostate biopsy who are at risk for local recurrence following radiotherapy.

Guidelines on the use of salvage radiation are often used for selecting men for cryoablation [48]. Specifically, these guidelines suggest that patients should demonstrate only localized recurrence without distant metastases, longer time interval (>2 years) between primary treatment and recurrence, PSA levels <10 ng/ml, PSA doubling time of >6–9 months, and a life expectancy greater than 5–10 years. These guidelines have been standardized for salvage cryoablation, and a study panel recommended men should typically have a PSA <15 ng/ml, clinical tumor stage T1c/T2a, Gleason score 3 + 3 or 3 + 4, a life expectancy of more than 10 years, and any prostate volume [28].

## Procedure, operative considerations, and technique of prostate cryoablation

### General considerations and patient preparation

A complete preoperative assessment is recommended for patients undergoing cryoablation and this includes anesthesia clearance, and appropriate cardiac and respiratory testing. Strict exclusion criteria for treatment, based on our experience, include uncontrolled bleeding diathesis or anticoagulant therapy that cannot be discontinued perioperatively. For those who can hold anticoagulants, these medications should be resumed within 24–48 hours following the procedure or after the urine clears, whichever is earlier.

A limited bowel preparation may be used, at the discretion of the practitioner, to free the rectum, however, there is no evidence that a bowel prep decreases treatment efficacy or decreases the rates of postoperative complications, such as infection. Standard antibiotic prophylaxis should be provided for no more than 24 hours in accordance with guideline recommendations and started within 1 hour of starting the procedure. Urethral strictures may need an internal urethrotomy or dilation and anal stenosis may require dilation in order to facilitate the insertion of a Foley catheter and the rectal probe, respectively, at the time of the procedure. Patients without a rectum or anal opening, such as patients who have undergone abdominal–perineal resection, are not suitable for cryoablation and other treatment modalities should be considered.

The last consideration prior to cryoablative therapy is the prostate gland volume. Men with very large glands are at higher risk of requiring multiple probes and are at increased risk of undertreatment. In this setting, neoadjuvant androgen-deprivation therapy (ADT) can be used to reduce gland volume prior to treatment. Specifically, neoadjuvant ADT has been associated with a mean reduction in prostate volume of 35% and tumor volume reduction of 50% within two months of treatment, although this rarely downstages the existing disease [49]. In one retrospective study, neoadjuvant ADT in men undergoing primary cryoablation (compared with those who did not get neoadjuvant ADT) demonstrated no significant differences in treatment outcomes or complications, with the exception of intermediate-risk men who had improved 5-year disease-free survival [50]. For these reasons, in our experience, we limit whole-gland cryoablation to men with prostate volumes greater than 80 g. For larger glands, we have used neoadjuvant ADT for size reduction for six months in men who could wait without high risk of disease progression.

### Operating technique

The patient is brought to the operative room and anesthesia is induced at the discretion of the anesthesia team. The patient is then positioned in the dorsal lithotomy position with appropriate padding, avoiding hyperflexion to minimize neuropraxia or injury. The lower abdomen, genitalia, and perineum are prepped using a betadine-based solution, and draped in the standard fashion. At this time, a transrectal ultrasound probe is introduced into the rectum and the prostate is carefully inspected. Measurements are taken of the prostate to calculate prostate volume. The ablation machine is calibrated for treatment and the precise location of probe insertion is determined. The simulation provides probe targets, and adjustment are made if needed to ensure that the final probe locations are sufficiently far away from the urethra and rectum to minimize injury and fistula.

Next a cystoscopy is performed to assess the urethra. In the absence of stricture, a glidewire is inserted into the bladder under direct visualization. A warming urethral catheter is then inserted into the bladder over the wire using the Seldinger technique. Temperature sensors are usually inserted at the apex, external sphincters, and neurovascular bundle to monitor freeze cycles (Figure 137.5; see also Video 137.1). The Onik maneuver is used to inject a combination of saline and local anesthesia (i.e. bupivacaine), intrafascially in Denonvilliers' to separate the rectum from the prostate. Our standard practice is to apply two freeze–thaw cycles, which are monitored under direct ultrasonic visualization and by temperature probe with the urethral warming catheter in place and functioning (Figure 137.5 shows the placement of probes and warming catheter) At the completion of the procedure, a urethral catheter is inserted into the bladder and is kept in place for a minimum of one week postoperatively. The patient is typically discharged home on the day of the procedure, with analgesia and the urinary catheter in place.

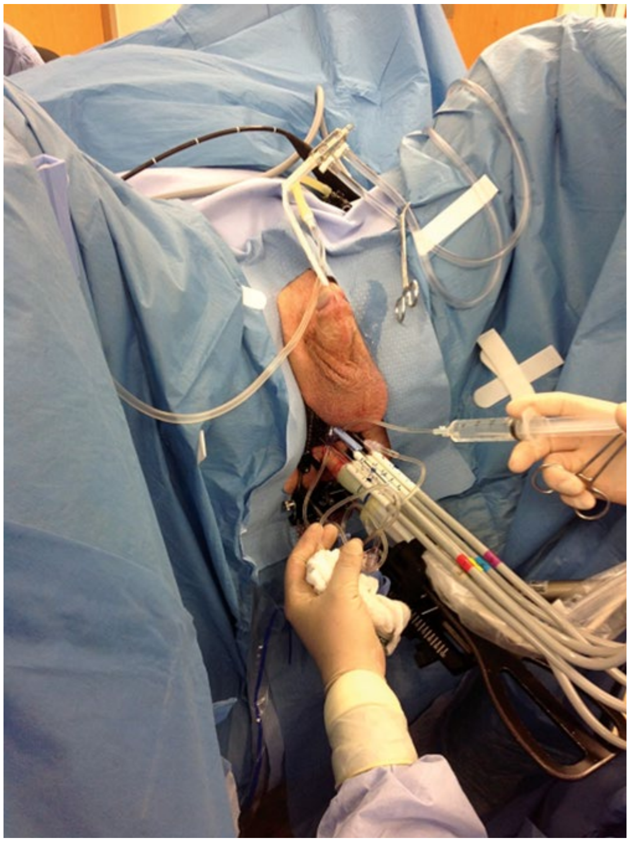

**Figure 137.5** Placement of probes and urethral warming catheter.

## Postoperative care

The most common complications in the more immediate postoperative period following cryoablation are urinary retention and pain, which can be managed with adjunctive medications at the discretion of the clinician.

### Follow-up: defining failure after cryoablation

Two major challenges are encountered in the follow-up of patients after cryoablation. With nonexcisional treatment for prostate cancer, like cryoablation, PSA does not completely become undetectable. Consequently, there are variable definitions of acceptable PSA levels following treatment, and current research is focused on defining PSA levels and kinetics that can better identify failure of therapy. The other challenge is deciding what triggers and criteria to use for ordering a prostate biopsy and how to interpret biopsy results after treatment. Lastly, these parameters differ in patients treated with partial or whole-gland therapy.

### PSA monitoring after cryoablation

Radiation therapy for prostate cancer currently relies on two criteria for identifying biochemical failure. The

ASTRO definition [51] has a sensitivity and specificity of around 60% and 72%, respectively [52], and the authors also looked at three other parameters that improved both sensitivity and specificity over the ASTRO definitions: a PSA > current nadir plus 3 ng/ml had a sensitivity of 66% and specificity of 77%; a PSA > absolute nadir plus 2 ng/ml was found to have a sensitivity of 64% and specificity of 74%; and two consecutive PSA increases of at least 0.5 ng/ml had a sensitivity of 67% and specificity of 78% [52]. The Phoenix definition was then described during a consensus conference in 2005 [53]. The ASTRO and Phoenix criteria, although widely used, have limitations and may delay detection of treatment failures [54].

Changing the PSA cutoff will understandably change the rates of biochemical failure. With the PSA cutoff set to >4 ng/ml, 68% patients were found to be free of biocchemical failure, but this dropped to 55% and 34%, respectively, when the PSA cutoff was lowered to >2 ng/ml or >0.5 ng/ml, respectively [55]. Bahn et al. also showed that when the PSA cutoff was raised from 0.5 ng/ml to 1 ng/ml, the biochemical disease-free survival rate rose from 59% to 69%, respectively [56]. An absolute PSA cutoff of <0.6 ng/ml has been recommended, and patients who demonstrated an initial PSA level of <0.6 ng/ml after salvage cryoablation had better (67% at 36 months) biochemical-free survival [57]. Others have suggested that a nadir PSA cutoff point of 0.4 ng/ml has better discriminating power [58, 59].

Biopsy-proven failures also correlate with PSA nadirs, and when the PSA nadir was <0.1 ng/ml, positive biopsies were noted in only 7%, but this rose to 60% when the PSA nadir was >0.5 ng/ml [60].

The Stuttgart definition of relapse was primarily developed in patients undergoing high-intensity focused ultrasound (HIFU), and is a variation of the Phoenix definition. Blana et al. stated that a PSA nadir plus 1.2 ng/ml and PSA velocity >0.2 ng/ml/year were found to be good predictors of recurrence [61]. A systematic review on salvage cryoablation noted that various series reported their results using PSA cutoffs of 0.3, 0.4, or 0.5 ng/ml, and the ASTRO and Phoenix definitions [62]. The Phoenix definition is more robust than the ASTRO definition, and correlated well with overall mortality [63], and is considered superior to ASTRO [54]. There is now a more sustained shift towards using the Phoenix definition for reporting on biochemical failure after prostate cryoablation.

PSA monitoring protocols have not been standardized. A recommendation by an international multidisciplinary consensus for design of clinical trials states that the PSA should be done quarterly for the first year, biannually for the second year, annually for the third year and then at the discretion of the center [28].

## Prostate biopsies

Prostate biopsies should become part of clinical trial protocols since almost 15% of patients could have cancer on the biopsy without having evidence of PSA recurrence [64]. Protocol biopsies are defined as biopsies that are done on all patients irrespective of the patient's PSA, at a certain point of time in their follow-up. The international consensus on trial design recommends a biopsy after initial inflammation has subsided and scar tissue has formed, and the authors suggest that this should be done 6–12 months after the cryoablation [28]. In a study on primary cryoablation, protocol biopsies were performed on all patients at six months and again as needed; 7.8% (8 patients) had elevated PSA and the biopsy was positive in only 1 patient [65]. Empiric biopsies are "without cause" biopsies that are done in the absence of a rise in PSA.

Biopsies should also be done when a biochemical failure is suspected, especially if the patient is being considered for salvage therapy. In a primary cryoablation study using the COLD registry, biopsies were performed in 28% of all patients: of these 38.4% were done for suspected recurrence based on PSA, while the remaining 61.6% were without cause biopsies done on an empiric basis [64]. When biopsies were done for suspected recurrence, 38% were found to be positive for cancer, while only 14.5% were positive for cancer in the empiric biopsy group [64].

The biopsies should be read and reported by an experienced genitourinary pathologist, since cryoablation-induced changes can pose challenges with interpretation. Studies have looked at biopsies after cryoablation, but many of these were done for suspected recurrence after salvage cryoablation, and the confounding effect of the previous radiation therapy induces bigger challenges in interpretation. Gooden et al. excluded patients with a prior history of radiation therapy and looked at biopsies in 30 patients who underwent primary cryoablation [66]. Recurrent or residual cancer was noted in 37% of patients, and these showed no therapy-induced changes. Unlike what is noted after radiation or after androgen-deprivation therapy, the effects of cryoablation mostly occur in the stroma, with acinar changes being uncommon [66]. Marked endothelial proliferation may, however, occur and special stains such as basal cell markers, AE1/AE3, and CD34/CD31 may be needed to differentiate between endothelial cells and cancer recurrence [66].

Since the pathologic changes mirror the necrosis and loss of glands with stromal fibrosis, residual glands may point to inadequacy of treatment in the corresponding areas. Studies have looked at the proportion of unchanged prostate epithelium in biopsies and this seems to correlate with residual cancer. Residual cancer was seen in

8,4% in biopsies having an average of 10% unchanged epithelium, but this rose to 43.6% when the normal epithelium per core was higher [67].

## Results

Results after primary and salvage cryoablation are summarized in Table 137.1. A review of literature has shown a lack of standardization in the reporting of treatment outcomes of different therapeutic options for prostate cancer. Perhaps this is one of the cancers where results should not be analyzed in isolation, as oncologic outcomes and postoperative complication rates are interrelated. Specifically, a wider field of treatment may lead to improved biochemical progression-free survival (BPFS), but at the expense of a higher complication rate. This is a result of the fact that cryoablation can induce collateral thermal damage to surrounding tissues. On the other hand, low complication rates noted with focal ablation are usually associated with higher rates of biochemical failure [19].

### Primary cryoablation

Primary cryoablation is increasingly being offered to many patients, and one recent large study looked at outcomes and predictors of biochemical failure [68]. In their study the overall BPFS at 5 years was 72.8% for 2242 patients who received primary cryoablation monotherapy.

**Low-risk category**

In the analysis of the COLD registry, 51.6% of patients had a Gleason score of 6 or less and 42.2% were classified as D'Amico low-risk patients, and the estimated 5-year BPFS for this group of patients was 82.6% [68]. In the study, the authors concluded that the pretreatment PSA, stage, Gleason score, and prostate volume were

BPFS, biochemical progression-free survival.

independent predictors of BPFS [68]. In another study on focal cryoablation, 56% of 41 patients were low risk, but the recurrence rate (biopsy or PSA criteria) described for the whole group of low- and intermediate-risk patients was 10%. In their study Bahn et al. reported on low- and intermediate-risk patients who underwent focal cryoablation. Of the 24 (33%) patients in the low-risk group, 6 had positive biopsies, but these were all found to be on the untreated side, reflecting an understaging effect of the pretreatment biopsy and the risk of focal therapy [42].

#### Intermediate-risk category

Cryoablation may have good efficacy in this group of patients. Bahn et al. described a biopsy-proven recurrence on the treated side in 1 out of 49 patients undergoing focal ablation for intermediate-risk disease [42]. They also noted five other positive biopsies in this group of patients, but these were noted to be on the contralateral, untreated side of the prostate [42]. Elshafei et al. described a 5-year estimated BPFS of 71.1% [68].

#### High-risk category

A recent study looked at 300 men with Gleason scores of 8 or more but localized T1 or T2 cancer, with failure defined using the Phoenix criteria. Their estimated 2- and 5-year BPFS was 77.2% and 59.1%, respectively, with continence in 90.5% and potency in 17% [59]. In another report from the COLD registry, the Kaplan–Meier 5-year estimate for this group was 57.8% [68]. For a group of 366 patients with clinical T3 disease, and using the Phoenix criteria, the estimated BPFS rates for whole-gland cryoablation, were 65.3% at 36 months and 51.9% at 60 months [43], and the use of neoadjuvant ADT improved these rates without reaching statistical significance [43]. Another study reported on 75 patients with cT3 disease and noted a 5-year BPFS of 48%, with BPFS of 55.6% for the T3a group compared to 36.7% for the T3b group [44].

### Salvage cryoablation

Many studies have looked at the results of salvage cryoablation, and BPFS rates range from 18% to 77%. However it is more common for the BPFS rates to be in the range of 45–55%. When the PSA nadir after treatment was set at <0.4 ng/ml, the 5-year estimated BPFS was 78.5% versus 17.9% when it was more than 0.4 ng/ml [58]. Compared with salvage radical prostatectomy, salvage cryoablation had a higher incidence of disease progression (23.5% vs. 16.7%) and a higher complication rate (23.5% vs. 16.7%), with urethral stricture being the commonest complication in this study [69].

## Complications and management

Cryotherapy-related complications are often due to unintentional thermal injury to adjacent tissues. We reviewed complications from available literature, and also looked at the COLD registry. Records of 6771 cases were available from 39 centers, and most of these had undergone primary cryoablation (whole-gland 4102, partial 1011).

The most commonly seen complication was erectile dysfunction with an incidence of 23.1–98.1% for primary and 50–100% for salvage cryoablation (Tables 137.1 and 137.2). Other common complications included perineal pain, tissue slough and urinary retention.

The wide variation in the incidence of erectile dysfunction and other complications is often due to lack of standardization in definitions, and difficulties seen with patient self-reported questionnaires such as the International Index of Erectile Function (IIEF-15) or the shortened version, the Sexual Health Inventory for Men (SHIM). Focal primary ablations demonstrate lower rates of erectile dysfunction [70] than salvage total ablations [71]; the etiology is multifactorial, with possible contribution from the effects' neurogenic and vasculogenic components. The effect of thermal injury to cavernous nerves [72], and the possible contribution from the vascular component [73], have been studied. Erectile dysfunction is more likely to occur with two freeze–thaw cycles than with one cycle (92% vs. 77%) [74], and recovery can be delayed up to 2–3 years after treatment and rarely even 5 years [75], with reported average recovery times of 16.4 months [76]. Recovery from erectile dysfunction depends on early penile rehabilitation, with multimodal therapy as needed (e.g. vacuum device along with regular use of oral medication for erectile dysfunction) [77].

Urinary retention is also more common after salvage cryoablation (0–21%) than after primary ablation (0–6%), and inflammation and prostate swelling [78] contribute to outlet obstruction. Indwelling urinary catheters and selective alpha blockade may help patients void reasonably following treatment. Clean intermittent self-catheterization may be required, but should be done with the understanding that in some cases it may cause urethral trauma and possible fistula formation. Some patients will require transurethral resection of the prostate (TURP), and suprapubic catheter placement for patients failing a second voiding trial is also an alternative [78].

Lower urinary tract symptoms, perineal pain, and symptoms secondary to tissue slough have common etiology arising out of direct effects of the freezing of the prostate and urethra, as a result of inflammation and tissue necrosis. Perineal and/or rectal pain has been

OIU, optical internal urethrotomy; TURP, transurethral resection of the prostate.

described to occur in 0–11% after primary cryoablation and 4–44% after salvage cryoablation. Tissue slough is described to occur in 0–6.7% of cases, but in the salvage series it is reported in 1.1–55%. The use of the newer generation machines [79] and urethral warmers [74, 80] reduces the incidence of these complications, and we believe that limiting the freeze time on the anterior probes also reduces the incidence of perineal pain. The perineal pain syndrome can be troublesome, and is often described as a burning sensation that can be associated with frequent bowel movements or rectal irritation [81]. Perineal pain can represent a significant cause for patient dissatisfaction following treatment [74]. Associated lower urinary tract symptoms may be noted, including irritative and obstructive voiding symptoms. The International Prostate Symptom Score (IPSS) overall symptom score and urinary bother score worsen in the first six months after cryotherapy, but return to baseline in 12 and 18 months, respectively [82]. Perineal pain can be managed conservatively, but transurethral resection of the necrotic tissue slough can speed up recovery [81]. Tissue slough is one of the main causes of retention and sometimes requires a TURP. When TURP is offered, it is important to recognize the risks of over-resection due to altered anatomy [80], and the higher risk of long-term incontinence. TURP should not be done earlier than three months following cryoablation [80]. In fact, the authors and many others reserve TURP until at least 12 months post treatment, especially in the salvage setting.

Less commonly, patients may develop urinary incontinence (1.6–9.5%), rectourethral fistulas (0–1.1% primary and 0–3.3% salvage), or urinary strictures and/or bladder neck contractures (0–3.3% primary and 0–4.2% salvage; 17% in one pooled series).

The risk of rectourethral fistulas increases from the primary (1%) to the salvage (2.8%) setting based on review of whole-gland ablation data from the COLD registry (unpublished data). Fistulas develop from freeze injury of the rectal wall [79], and the incidence has markedly decreased with the improvement of ultrasonography for imaging iceball formation during the procedure. Freezing injury can be compounded by poor quality in prior irradiated tissues, which may explain higher rates of fistula in the salvage setting, reported as high as 11.1% in some series. It is important to note that the rates of fistula decrease in the hands of an experienced surgeon, with most of the fistulas occurring in the first 25 cases of most surgeons' series [79]. Patients with fistulous disease most commonly present with watery discharge per rectum or "diarrhea" [81]. In addition, patients may present with classic urinary symptoms such as recurrent urinary tract infection, fecaluria, or pneumaturia.

The diagnosis of rectourethral fistula starts with a thorough history and examination, followed by evaluation of the defect via a combination of imaging (i.e. CT cystography or retrograde urethrogram/cystogram). Cystoscopy, with possible sigmoidoscopy, can also be considered at the discretion of practitioners based on patient symptoms. Early management should involve drainage of the bladder with a urinary catheter. In fact, some series have demonstrated that small defects may heal with prolonged (up to three months) drainage [81]. Our own preference at our institution is urinary drainage for 6–12 weeks, and we have reported treatment of a postablation fistula with urinary catheter and temporary fecal diversion [83]. In patients requiring more complex repairs, two principles should be considered – urinary diversion [84] and fecal diversion [85] – in addition to repair and coverage of the defect with a flap (i.e. omental, gracilis, etc.).

The incidences of urethral stricture and bladder neck contracture also increase from the primary to the salvage setting. Stricture disease occurs due to tissue injury during therapy and may be affected by prior irradiation or concomitant infection at the time of treatment. Furthermore, fistulous disease may cause stricture disease, further complicating the clinical picture and future repair [84]. Warming urethral catheters have been show to decrease the rate of tissue sloughing after cryoablation [74, 80]. Treatment is dependent on the length of the stricture and assessment of the defect by retrograde urethrography should only occur after three or more months of urethral rest. Shorter strictures may be managed by dilation or urethrotomy; however, urethroplasty may provide a more efficacious and durable response for both short- and long-segment urethral strictures. Severe bladder neck contractures may require aggressive incision and artificial urinary sphincter for management.

Lastly, the rates of urinary incontinence have decreased dramatically with advances in cryoablative technologies [79]. And the fluctuation in the rates of incontinence reported by different series may reflect differences in the definitions of incontinence used [76]. Incontinence may result from various causes following cryoablation, including damage to the external sphincter mechanism and new-onset bladder overactivity. Similarly to the other complications, prior radiation can lead to higher rates of incontinence in men undergoing salvage cryoablation [80].

Urgency incontinence is reported in up to 80% of patients with long-term incontinence [78]. It is important to note that recovery of continence may be a long process, taking up to 6.1 months [76]. Care must be taken to avoid transurethral resection of tissue slough after cryoablation in men with obstructive symptoms, as resection may potentiate incontinence and complicate management [86]. A series by Cespedes and colleagues showed that 13 of the 15 patients who developed obstruction became incontinent either after a TURP or after spontaneous passage of slough [80]. Urethral warmers have been shown to be associated with less frequency and severity of incontinence [74, 80]. Management of incontinence should be conservative, starting with lifestyle modification, pelvic floor exercises and therapies, and overactive bladder medications (i.e. anticholinergic or beta-3 agonists). However, in patients who fail conservative therapies, full evaluation with cystoscopy and pressure-flow studies may be required prior to considering more invasive therapies such as artificial urinary sphincter [74].

Extremely rare complications of cryoablation have been described in the literature and include death [87], transient ichemic attack/stroke [81], acute renal failure [87], and hydronephrosis secondary to ureteral obstruction [81, 87]. In addition, a very small proportion of men have described a feeling of penile tingling/numbness [18, 88], which was managed conservatively. Other rare complications include hematuria [78], scrotal anomalies (i.e. swelling or hematoma) [78, 81], urethrocutaneous fistula [89], and infective complications such as epididymitis [87] and abscess [75, 78, 90–92].

## Conclusions

Cryoablative therapy is increasingly used for men with localized prostate cancer as a treatment option both in the primary and salvage setting (Tables 137.1 and 137.2). Treatment outcomes demonstrate an acceptable oncologic outcome with a durable response, as evidenced by recent publications with intermediate follow-up. However, more time is needed to assess the long-term impact of current ablative therapies on postoperative functional and oncologic outcomes. Nonetheless, in carefully and informed patients, cryoablation is an acceptable therapy for prostate cancer.

## Acknowledgments

We gratefully acknowledge Dr. Ahmed Elshafei, Research Associate, for relevant data from the COLD registry.

## Introduction

Imaging in endourology is mainly composed of grayscale ultrasound, X-ray, computed tomography (CT), magnetic resonance imaging (MRI), and skeletal scintigraphy. All of these modalities have their own place in urology; however, in this chapter we focus on contrast-enhanced ultrasound (CEUS) as it compares with MRI and CT imaging.

CT scans are commonly used in the diagnosis, staging, and follow-up of urologic malignancies. In the diagnosis of kidney tumors, ultrasound is mainly used for a first screening and, in most cases, CT is utilized to make the final diagnosis. MRI is commonly used to evaluate adrenal tumors and cystic lesions in the kidney, and to stage renal cell and prostate carcinoma. For some of the urological indications, MRI is used when CT is contraindicated.

Drawbacks of CT and MRI relate to their costs, limited availability, and impractical use at the bedside. Furthermore, CT and MRI contrast agents can have side-effects [1, 2]. CT contrast agents are iodine-based and these agents can worsen the existing renal function in patients with renal insufficiency [1]. CT is also associated with radiation exposure. Although MRI does not expose patients to ionizing radiation, its contrast agents are often gadolinium-based and can cause nephrogenic systemic fibrosis in patients with severe renal failure [2].

Ultrasonography is a safe method to investigate the kidney, bladder, prostate, scrotum, and penis. It has high resolution, allows real-time imaging and is widely available, cost-effective, and highly compatible with therapeutic equipment.

For diagnosing scrotal abnormalities, ultrasound is the investigation of choice. When used appropriately, ultrasound can distinguish between the most common scrotal abnormalities [3]. Doppler ultrasonography allows further discrimination of these abnormalities, since it can directly evaluate testicular perfusion. However, the diagnostic accuracy of grayscale and Doppler ultrasound for malignant processes of the kidney, bladder, and prostate is low. For the bladder and for the kidney, it is mainly used as a screening tool, and for prostate cancer, its main role is to guide systematic biopsies.

Malignancies are associated with angiogenesis and neovascularization and, therefore, changes in perfusion [4, 5]. The visualization of this process may increase the sensitivity and specificity of tumor detection as well as the accuracy of staging. Suitable techniques for perfusion imaging are dynamic contrast-enhanced MRI, contrast-enhanced CT, and CEUS.

CEUS was first observed in 1968 during imaging of the aortic root [6]. After an injection of saline, it was noted that the small air bubbles, present in the saline, significantly enhanced the ultrasound signal. Attempts to use free air bubbles as an ultrasound contrast agent have been conducted, but the short lifetime of these bubbles proved to be a problem. More recently, small ($<8\,\mu m$) encapsulated gas-filled microbubbles have been developed as new ultrasound contrast agents. Because of the presence of a shell, these contrast agents have a lifetime of several minutes, allowing contrast visualization of organs with a simple intravenous injection. The first application of CEUS was in cardiology for the visualization of myocardial perfusion, but its usage is currently extended to image the liver, breast, kidney, and prostate [7].

When microbubbles are exposed to sound waves, they are compressed and subsequently expanded as a result of the changing ultrasound pressure. With low-energy ultrasound waves, the bubbles expand linearly and behave like additional bloodstream reflectors, resulting

in increased reflected ultrasound energy. This mode is especially useful in Doppler ultrasound imaging [8].

With medium-energy waves, the bubbles expand nonlinearly, which results in reflected signals that not only encompass the transmitted ultrasound frequency, but also additional harmonics. Currently, contrast-specific imaging techniques are available that utilize these harmonics to distinguish between the reflections of the bubbles and tissue. Hence, sensitive imaging of perfusion is possible.

At high energy, still within the normal clinical range, the bubbles will disrupt in the imaging plane, providing the opportunity to visualize a new inflow of contrast *in situ*. This technique, which is very useful to assess perfusion, is referred to as destruction–replenishment [9].

A wide range of ultrasound contrast agents are commercially available [10]. These agents have been extensively used for years and only in very few cases have side-effects been reported. The most commonly reported side-effects are usually transient: altered taste, pain at the side of injection, and generalized flushing [10]. The most severe adverse effects were allergic reactions to the administered substance [11]. In general, ultrasound contrast agents are considered to be safe [10, 12].

## Contrast-enhanced ultrasound of the prostate

Prostate carcinoma (PCa) is the most common malignancy in the male population in the western world, and accurate diagnosis and staging is still a clinical challenge [13, 14].

Transrectal ultrasound (TRUS) was introduced in 1968 by Watanabe et al. [15]. Currently, TRUS is mostly used for guiding systematic biopsies. At first, only hypoechoic lesions were considered as target for biopsy to identify PCa. However, it was demonstrated that these lesions only have a 17–57% chance of being malignant and that up to 30% of the prostatic malignancies are isoechoic [16]. Hodge et al. described the introduced ultrasound-guided sextant biopsy protocol, with a sensitivity and specificity in the range of 39–52% and 81–82%, respectively [16, 17]. The guidelines currently recommend a ≥10-core biopsy protocol [18]. However, biopsies are associated with a considerable risk of complications [19] as well as underdiagnosis; in up to 30% of the patients that are referred for repeat biopsy after negative outcome in the first procedure, malignancies are found [20].

As stated previously, malignancies are characterized with angiogenesis and neovascularization, and therefore an increased microvessel density (MVD) [5]. Siegal et al. reported an approximate twofold increase in MVD in prostate carcinoma in comparison to benign prostate hyperplasia [21]. In 2001, Sedelaar et al. correlated the histologically determined MVD in radical prostatectomy specimens with three-dimensional contrast-enhanced power Doppler [22]. On average, the areas with increased enhancement had a 1.93 times higher MVD than unenhanced areas, and all enhancing areas contained PCa. Only small satellite lesions (1–2 mm) were not identified on CEUS. This study clearly demonstrated that the increased MVD as a result of PCa can be visualized with CEUS (Figure 138.1), opening the door to biopsy targeting by CEUS.

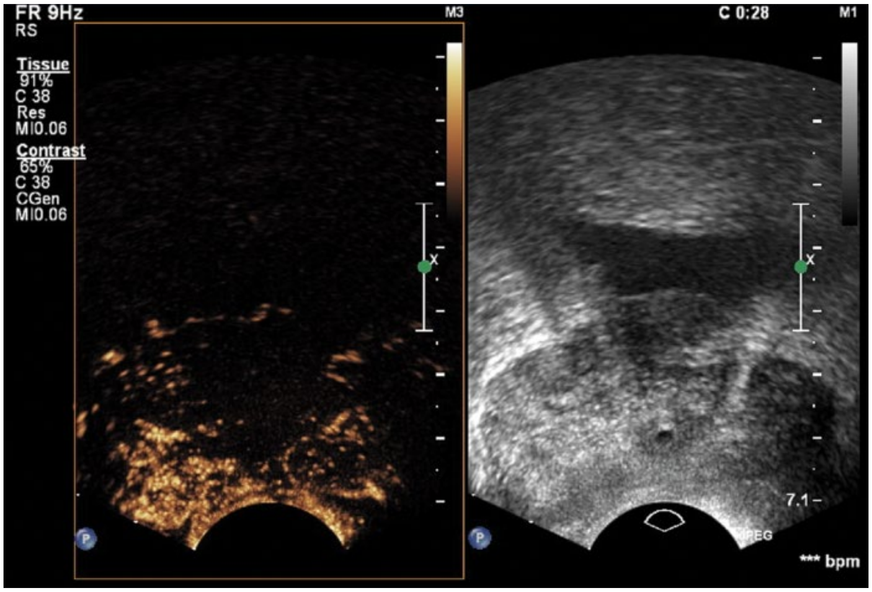

**Figure 138.1** Contrast-enhanced ultrasound investigation of the prostate with an enhancing lesion on the left side in the image. Histopathologic examination showed a Gleason 3+4 carcinoma.

## Targeted biopsies

The value of CEUS as a guiding tool for targeted biopsy has been extensively studied in recent years. In general, the PCa detection rate *per biopsy core* is significantly higher for targeted than for systematic biopsies. Zhao et al., for example, reported a per core PCa detection rate of 75% for CEUS-targeted biopsy, compared to 48% for systematic biopsy in 28 patients with confirmed PCa [23]. The sensitivity of targeted biopsy in the entire group of 65 patients with elevated prostate specific antigen (PSA) level and/or abnormal digital rectal examination was 79%; with false positives due to benign prostate hyperplasia and prostatitis, and false negatives for small-size or transitional zone foci. In a comparable study, Linden et al. found a similar relation for the detection rate per biopsy core (8.3% for systematic and 13% for targeted biopsy) in a group of 60 patients that were referred for biopsy [24]. These studies, however, also reported a small fraction of patients for whom PCa was only identified by systematic biopsy.

Contrast-enhanced Doppler ultrasonography was used in several studies on targeted biopsy. Peltzer et al. investigated 380 patients with a PSA level between 4 and 10 ng/ml and a free-to-total PSA level less than 18% with systematic and CEUS-targeted biopsies [25]. There was no significant difference (104 vs. 105 carcinomas out of 143 carcinomas), but the combination of CEUS and systematic biopsies was significantly more effective in detecting carcinoma than either modality alone. Mitterberger et al. compared the efficiency of 10-core systematic biopsy versus a 5-core targeted biopsy in 1776 men with a serum PSA concentration greater than 1.25 ng/ml [26]. The PCa detection rate of targeted biopsy (961 of 8880 cores) was higher than that of systematic biopsy (910 of 17 760 cores). Cancer was detected in 559 patients; in 149 cases only the CEUS-targeted biopsies returned positive, in 83 only the systematic ones. Another study on the use of contrast-enhanced Doppler (300 patients, PSA level greater than 2.5 ng/ml) did not find a significant difference in detection rate compared to systematic biopsy [27]. All of these authors concluded that for maximal detection, a *combination* of systematic and CEUS-guided biopsies is preferred.

In 2013, a meta-analysis on CEUS was published that incorporated 16 studies with a total of 2624 patients [28]. It was demonstrated that CEUS had high potential with an overall sensitivity and specificity of 70% and 74%, respectively. The technique was not yet considered sufficiently accurate to replace systematic biopsy. A more recent systematic review on targeted biopsy, incorporating a few CEUS studies mentioned in this section, indeed concluded that the combination between targeted and systematic is most reliable in terms of detection rate [29].

In summary, CEUS is a promising diagnostic tool for PCa localization. The PCa detection performance is comparable with that of systematic biopsies with fewer biopsies needed, and the detected cancers are of higher Gleason grade [30]. When CEUS is compared with histological specimens after radical prostatectomy, it frequently detects the index tumor. Prospective multicenter trials are still needed to confirm these results.

## Use in focal therapy

In the 2014 multidisciplinary consensus on trial design for focal therapy, CEUS is mentioned as one of the recommended imaging tools [31]. Due to its reliable assessment of tissue destruction, CEUS is increasingly used to guide and monitor the application of many focal therapeutic modalities. Here, we mention high-intensity focused ultrasound (HIFU), interstitial laser therapy, irreversible electroporation, and anti-androgen therapy.

Sedelaar et al. used CEUS to investigate the effectiveness of HIFU in the treatment of PCa [32]. In this study, CEUS was compared with whole-mount histology specimens from patients who underwent a radical prostatectomy 1–2 weeks after HIFU treatment for a T1 or T2 prostate carcinoma. Overall, a strong correlation of 0.98 between CEUS and pathology volumes of the lesion was found. In another study, Rouvière et al. found that the 30-day post-HIFU CEUS findings in 28 patients were in good agreement with biopsy outcomes and MRI acquisitions [33]. They concluded that CEUS was a promising tool to discriminate devascularized and viable regions after treatment. However, the interference of microbubbles with HIFU should be investigated before allowing immediate repeat of this procedure after CEUS.

Atri et al. applied real-time CEUS monitoring during interstitial laser therapy in 12 patients [34]. After one week, the treatment effect was quantified by means of the ablated tissue volume, which was in good correspondence with complementary MRI scans. Another study on laser photothermal focal therapy involved real-time CEUS to follow the size development of hypovascularized lesions, but also MRI in the follow-up [35].

In a study on irreversible electroporation by Van den Bos et al., involving 16 patients who were scheduled for prostatectomy, the treatment effect was monitored by both T2 MRI and CEUS [36]. The measured sizes of the ablated areas closely resembled those in the histopathological examination, with Pearson's correlation indices of 0.88 and 0.80, respectively.

These studies demonstrate that CEUS is able to reliably assess the treatment effect of focal therapies in real-time and follow-up monitoring. In view of this, CEUS has been hypothesized to be a suitable alternative also to contrast-enhanced MRI in cryotherapy and photodynamic therapy [37]. Up until now, however, the focal treatment of patients with localized PCa is not yet considered standard procedure due to the limitations in visualization and patient selection.

### Combined contrast-enhanced ultrasound

Recently, the use of CEUS in combination with other ultrasound modalities has been considered for the localization of prostatic malignancies [38].

After performing CEUS and grayscale TRUS, Matsumoto et al. were able to localize at least one focus in 40 of the 50 (80%) patients with biopsy-proven PCa. This was more than based on the grayscale (40%) or the contrast scan (62%) alone [39]. Also the combination of CEUS with grayscale TRUS and Doppler imaging was studied [40]. A PCa detection performance of 82% was observed after evaluation with a 10-biopsy protocol in 150 patients, compared to the detection rates of 51%, 48%, and 73% at cancer sites for TRUS, Doppler, and CEUS individually.

Promising results were also found for the combination between CEUS and elastography, which is the measurement of tissue stiffness upon cyclic manual compression. In a targeted biopsy study, the detection rate of this combination exceeded the rate that can be expected from systematic biopsies [41]. Alternatively, CEUS imaging of PCa regions that were marked as suspicious based on real-time elastography led to a decrease in histologically confirmed false positives, improving the positive predictive value from 65% to 90% [42].

All multiparametric or multimodality ultrasound approaches with CEUS, however, are still under development.

## Contrast-enhanced ultrasound in renal masses

The more frequent use of cross-sectional imaging has resulted in an increase of incidentally found renal masses. Renal masses are divided into solid and either simple or complex cystic masses. Approximately 10% of renal cell carcinomas present as complex renal cysts, but not all complex cysts are renal cell carcinomas [43, 44]. To characterize renal cysts, the Bosniak classification scale is generally used [45].

Conventional ultrasound imaging cannot perfectly differentiate between complex cysts that need surgery and those that can be observed. Currently, the decision is primarily based on the enhancement characteristics of the cyst and in most cases a contrast CT is used to image these characteristics. Contrast-enhanced MRI is traditionally utilized when CT is not possible, but also CEUS recordings are increasingly performed [46].

After administration of the ultrasound contrast agents, the kidney displays fast and intensive enhancement. In 2004, Thorelius used CEUS for various organs, observing a high sensitivity in the characterization of nonvascular lesions (e.g. cysts, infraction, and laceration) in the kidney [47]. The most recent EFSUMB guidelines on the clinical practice of CEUS recommend its use to differentiate solid lesions and cysts, discriminate tumors and “pseudotumors,” characterize complex cystic masses, and monitor ablative treatment [48].

### Diagnosis of renal masses

In the diagnosis of renal masses, imaging is primarily applied for the differentiation between malignancy (predominantly renal cell carcinoma) and benign lesions such as angiomyolipoma, oncocytoma, cysts, and “pseudotumors” [49].

Many studies found that CEUS was not inferior or even better to the traditional contrast-enhanced CT [49]. In a 2007 pilot study, Wink et al. performed CEUS in 18 patients and were able to classify all 20 renal masses correctly [50]. Of 13 masses for which histology was available, 12 proved to be malignant. Of the other 7 masses, 4 were classified as Bosniak I or II(F) cysts, 2 as angiomyolipomas, and 1 was suspicious of renal cell carcinoma. Figure 138.2 shows an example of CEUS of a renal tumor.

Quaia et al. investigated 26 patients with renal masses in whom they compared the CEUS recordings with histology or CT [51]. Of the 26 masses found, 19 were solid renal masses, of which 11 solid renal cell carcinoma, 7 angiomyolipoma, and 1 embryonal metanephric adenoma. CEUS and CT were equally good in the differentiation between solid renal cell carcinoma and angiomyolipoma.

Park et al. compared the performance of CEUS and CT in the diagnosis of cystic renal masses and found that 6 of the 19 patients with solid components were only identified with CEUS [52]. Furthermore, Ascenti et al. examined 40 patients with one or more cysts of Bosniak class II or higher and reported a complete concordance between CEUS and CT in discriminating between nonsurgical and surgical cysts [44]. In a study with 103 patients displaying complex cystic masses, Xue et al. found CEUS performed better than contrast-enhanced CT and ultrasonography in terms of visualizing the septa and wall thickness [53].

CEUS is also a valuable modality for the imaging of peritumoral pseudocapules, which are associated with low-risk tumors and are conventionally identified with MRI [54]. Ascenti et al. investigated CEUS in 32 patients with 40 renal masses, of which 26 were renal cell carcinoma [55]. On histological examination of the renal cell carcinomas in 14 of the cases, a pseudocapsule was

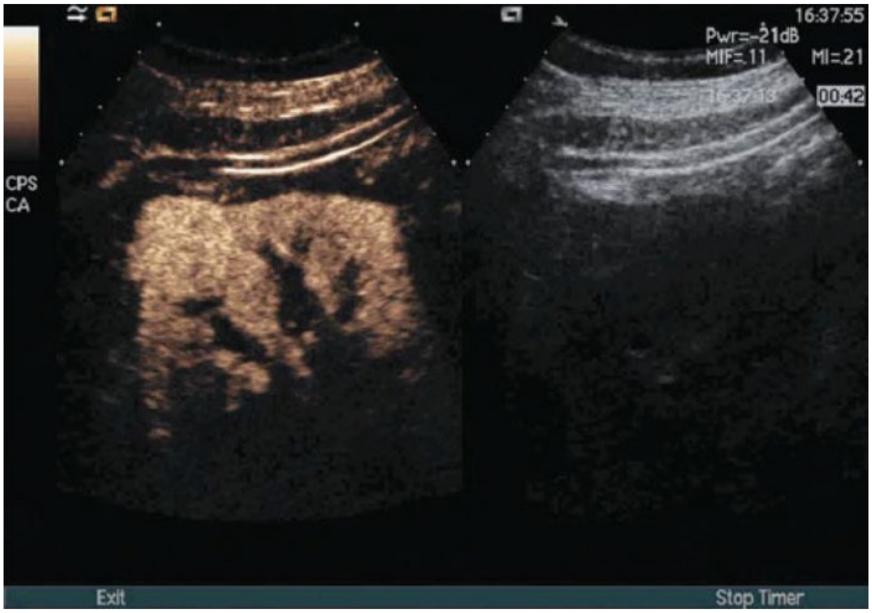

**Figure 138.2** Contrast-enhanced ultrasound investigation of a kidney tumor. On the left side in the image an enhancing lesion is seen.

present. Conventional ultrasound detected this in 3 cases with a sensitivity of 21%, and CEUS detected this in 12 cases with a sensitivity of 87.5%.

Larger scale studies also underline the value of CEUS in the diagnosis of renal masses. Barr et al. carried out a retrospective study from 1999 to 2010 on the performance of CEUS in 721 patients with indeterminate renal masses and evaluated the tumor detection in the 306 patients that received definite diagnosis [56]. Due to five false positives, they reported a sensitivity and negative predictive value of 100% and a specificity and positive predictive value of 95%. In addition, a recent meta-analysis on the ability of CEUS to detect renal cell carcinoma investigated 11 studies and 880 patients and found a sensitivity and specificity of 88% and 80%, respectively [7].

## Use in ablative therapies

As a result of the increasing incidence of small renal masses, of which a significant number are benign or low risk, nephron-sparing treatment modalities have been introduced. Along with partial nephrectomy [57], ablative treatments such as cryoablation [58] and radiofrequency ablation (RFA) [58] can be used. Similarly to the focal treatment of the prostate, CEUS could play a substantial role in the monitoring or follow-up of these treatments, by visualization of the resulting perfusion defects.

Meloni et al. compared CEUS with contrast-enhanced CT or MRI after RFA in 27 patients with 28 tumors. At baseline imaging, 27 of these tumors exhibited a hypervascular pattern and one a hypovascular pattern [59]. The concordance between CEUS and CT or MRI findings after RFA was 100% for the hypervascular tumors; the one case of the hypovascular tumor progression was missed on CEUS. In addition, Hoeffel et al. and Allard et al. compared CEUS versus CT in, respectively, 66 and 37 patients who were treated with RFA [60, 61]. The scans were interpreted by multiple independent, blinded radiologists and, again, high concordance was found between CEUS and the current gold standard.

CEUS was also tested as a surveillance tool after cryoablation treatment. Zhu et al. performed CEUS, CT, and MRI in three patients before and after the procedure [62]. The CEUS images demonstrated the same enhancement patterns as CT or MRI, but CEUS demonstrated a better visualization of the arterial feeding vessels. Wink et al. evaluated CEUS in the follow-up in seven randomly selected treated patients [63]. Even though the contrast recordings were not always taken on the same day as CT and MRI scans, a high concordance was found in the long-term follow-up. Also, Barwari et al. and Zeccolini et al. observed a high correspondence between CEUS and CT in the cryolesion assessment after (laparoscopic) renal cryoablation in 26 cases and 25 cases, respectively, and deemed the technique a proper alternative in the long-term follow-up [64, 65]. An example of CEUS after cryoablation is shown in Figure 138.3.

Especially for ablative treatment modalities, the latest studies suggest that CEUS is a viable alternative for contrast CT or MRI. The absence of perfusion can be visualized with a high sensitivity. Again, prospective multicenter trials are needed to fully establish the clinical additional value of this technique.

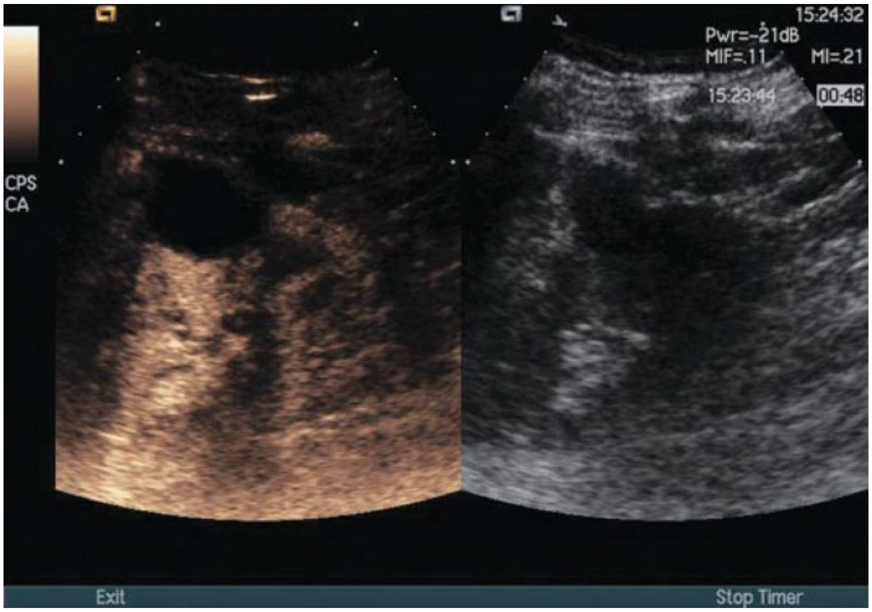

**Figure 138.3** Contrast-enhanced ultrasound image of a kidney after cyroablation. A clear avascular zone is visible in the location where the cryoablation was performed.

## Future developments

### Quantification

In general, the described use of CEUS permits a subjective determination of perfusion features by the investigators, and may therefore be subject to bias between centers and investigators. More well-defined and objective perfusion measures have been investigated. This quantification is often based on measured time-intensity curves (TICs) – the evolution of enhancement over time.

The crucial changes in the vasculature due to angiogenic PCa are reported to cause more rapid and strong enhancement compared to benign regions in the prostate [66]. This has been quantified by extracting features such as the bolus arrival time, maximum enhancement, and the wash-in gradient from the TICs [67]. A study by Goossen et al. indicated that the minimal time-to-peak enhancement was the most predictive factor to determine the affected side with malignancy in patients with proven PCa [68]. Postema et al. studied the wash-in rate to predict PCa biopsy outcome and found the use of this measure to increase the detection rate compared to the CEUS videos alone [69]. Instead of looking at the perfusion characteristics, the local dispersion kinetics of the contrast bolus can also be assessed. Several dispersion-related parameters were found to be excellent markers for PCa confirmed in corresponding radical prostatectomy specimens, yielding receiver-operating characteristic curve areas of 0.88 [70], 0.91 [71], and 0.92 [72]. An example is presented in Figure 138.4. These technologies are currently under investigation as a guiding tool for objective, standardized targeted biopsy.

Similar quantification techniques have been proposed for renal masses. The value of wash-in and wash-out characteristics to identify malignant and benign masses, for example, was evaluated by Eisenbrey et al. [73]. Indeed, Cai et al. found that correctly chosen thresholds for the enhancement intensity at 60 seconds and the wash-out time were able to discriminate malignant and benign masses [74].

Recent development of three-dimensional techniques to record or quantify CEUS measurements might boost its usefulness even more. Wei et al. showed that the application of CEUS in three dimensions visualized more intratumoral and tortuous branches in renal carcinoma [75]. Similar results are shown for acoustic angiography [76]. Furthermore, three-dimensional quantification, for example for dispersion imaging, is likely to improve the reliability of CEUS as a guiding tool for targeted biopsy of the prostate [77].

### Targeted microbubbles

Even more specific imaging of malignancy becomes possible with the development of targeted contrast agents (e.g. microbubbles with targeting ligands added to their coating). These adhesion molecules bind to biomarkers of angiogenesis, for example, such as vascular endothelial growth factor (VEGF) and $\alpha_v\beta_3$ integrin [78].

Particularly promising is the targeting of VEGF receptor type 2. In an *in vitro* study with mouse cell cultures with cancer and noncancer cells, Willmann et al. found that VEGF-targeted microbubbles adhered significantly more to the malignant cells than to a control sample of nontargeted microbubbles (2.1 bubbles per

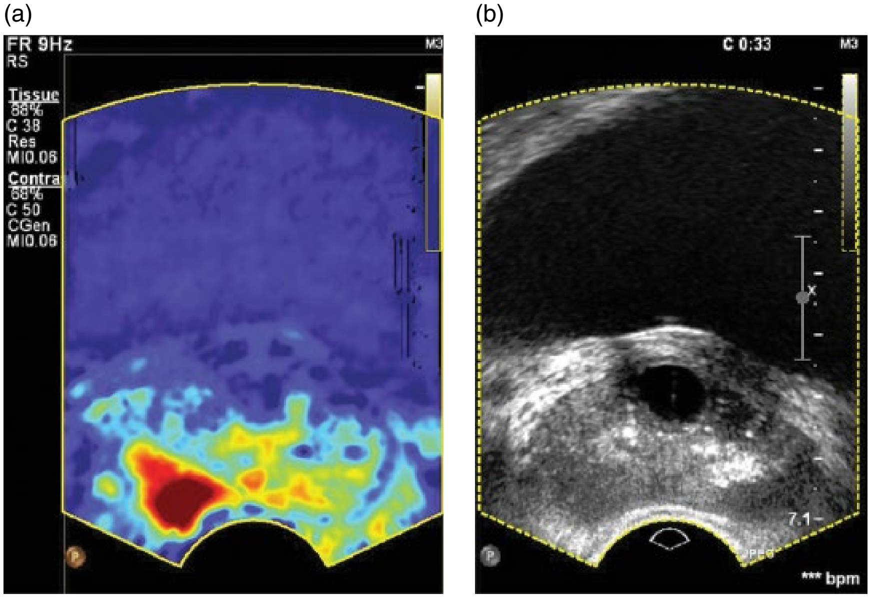

**Figure 138.4** Quantification of contrast-enhanced ultrasound with contrast ultrasound dispersion imaging. (a) Contrast-enhanced ultrasound with an overlay of the quantification results. The red areas are predicted to have a high chance of being malignant. (b) Normal B-mode grayscale image.

cell compared to 0.1–0.01 bubbles per cell) [79]. Cancer cells were also significantly more adhered to than non-cancer cells. Subsequently, these microbubbles were tested during CEUS measurements in *in vivo* murine models. Willman et al. [79], Lyshchik et al. [80], and Wei et al. [81] all observed a statistically significantly higher contrast intensity for the targeted agents than for the control agents in mice implanted with angiosarcoma, mammary carcinoma, and renal carcinoma, respectively.

In 2010, the VEGF-targeted contrast agent BR55 (Bracco Diagnostics, Milan, Italy) was introduced for use in humans [82]. After investigation in rat prostate and a successful Phase 0 trial [83], the first clinical trial for the diagnosis of prostate cancer using these targeted contrast agents has recently been carried out [84].

The amount of binding of these targeted agents (and thus the degree to which the targeted biomarkers are expressed) is usually assessed using destruction–replenishment techniques [79–81]. These methods involve a high-energy disruptive ultrasound pulse being delivered to the area after allowing the targeted microbubbles to fully bind. Since the subsequent contrast signal is only coming from freely circulating contrast agents refilling the vessels, the difference between the signal before and after said pulse can be used as a measure for the molecular binding (i.e. targeted differential enhancement) [85]. Promising new techniques for quantitative binding assessment are being developed by modeling the first-pass binding kinetics of these contrast agents [86].

## Drug delivery with ultrasound microbubbles

Manipulation of the contrast microbubbles also enables local ultrasound-mediated drug and gene delivery. This can be performed by either (i) using a high-intensity ultrasound pulse to destruct the microbubbles and locally rupture the capillary walls (sonoporation), resulting in the increased uptake of a drug that was co-injected in the bloodstream; or (ii) using the microbubble as a carrier and initiate bubble disruption with a high-output ultrasound pulse to release its payload [87]. For this, the pharmaceutic agents or plasmids can be encapsulated in the gas core or incorporated in the microbubble shell.

These approaches are especially important for gene delivery. The first approach was used by Koike et al. to nonvirally transfect rat kidneys with luciferase, while mixed with microbubbles under the application of ultrasound [88]. This way, up to 80% of the cells were transfected and this correlated well with the microbubble concentration. Lan et al. used a similar procedure and reported up to a 1000-fold increased transgene expression compared to non-ultrasound treatment [90]. Following the second approach, Haag et al. assessed whether a DNA particle could be transfected in to human prostate carcinoma cells [89]. Initial *in vitro* experiments revealed that 49% of the cells contained the DNA particles. Subsequently, ultrasound with contrast agents were successfully used to intratumorally and intravenously transfect DNA into mice with human PCa.

The relevance of ultrasound-mediated drug delivery techniques is expected to grow with the advances in drug treatments. The development of new microbubble contrast agents, such as nanoscale droplets that can be used both for imaging and therapy [90], also supports the progress of this kind of therapeutic modalities.

### Fusion imaging

Over the last years, CEUS has become a reliable technique for imaging of perfusion and associated diseases. New MRI developments for cancer detection and localization, such as multiparametric MRI for PCa [92], also show promising results in centers of expertise. The fusion of recorded MRI studies and real-time CEUS for PCa-targeted biopsy is technically feasible and has clinically acceptable accuracy [93]. First tests with targeted biopsy under MR/CEUS fusion guidance have been conducted with promising results [94].

In the same way, CT and ultrasound or CEUS can be combined. In 2008, Ukimura et al. used fusion imaging to guide RFA treatment of renal cell carcinoma [95]. They found that fusion imaging provided excellent anatomical visualization and a precise target of RFA. Even the combination of MRI, CT, and CEUS for imaging of renal cell carcinoma has been applied using electromagnetic field tracking [96], although this procedure is still in a very early stage of development.

## Conclusions

In centers of expertise, CEUS has shown promising results in diagnosis and treatment imaging of prostate and kidney cancer through the visualization of perfusion. The available results for monitoring and follow-up of focal (ablative) treatment modalities are also very encouraging, especially as it provides a safer alternative to ionizing renal CT acquisitions and the use of CT/MRI contrast agents that can cause renal failure. Large prospective and multicenter studies should provide the final evidence that CEUS has an additional clinical value. With the progress in targeted molecular imaging, the development of fusion techniques, and the introduction of standardized as well as objective quantification, the role of CEUS is expected to grow in the coming years, leading to even more accurate imaging of malignancies and ablative treatment effects.

## Introduction

Prostate cancer (PCa) is currently the most common solid organ cancer type among men in the western world, with a lifetime risk of approximately 1 in every 6 individuals. However, it is a slowly progressing disease; only around 1 of 36 diagnosed patients will eventually die from PCa [1, 2]. Early detection of PCa is important since treatment of localized disease can be curative. In the era of prostate specific antigen (PSA) screening, more patients are being diagnosed with PCa and these are often of the indolent type. This results from random biopsies of the prostate gland detecting low-grade, microscopic cancer that will take years to grow and may even never become symptomatic. One solution to this quagmire is to use imaging to detect only the most dangerous lesions.

Currently, most predictive nomograms fail to include imaging; they rely on demographics (age, family history) and clinicopathologic features (serum PSA, Gleason score at biopsy). However, such an approach, combined with random biopsy, can easily miss significant cancers while detecting many insignificant cancers. Conventional imaging techniques such as computed tomography (CT), transrectal ultrasound (TRUS) are of limited value for detection and staging of localized PCa. Consequently, multiparametric magnetic resonance imaging (mpMRI), which includes both high-resolution anatomic and functional pulse sequences, has begun to play a major role in the detection and staging of localized PCa [3, 4]. In this chapter, we will review the specific components of prostate mpMRI, how these can be used in the diagnosis and staging of localized PCa, guidelines for interpreting mpMRI, and use of mpMRI in targeted biopsy.

## Multiparametric magnetic resonance imaging

Multiparametric MRI has greatly improved the identification and staging of localized PCa. With the advent of higher field strength magnets (3 tesla), new coil designs (endorectal and multichannel phased array surface coils), modern MRI sequences have gained increasingly higher resolution. This not only allows for more accurate cancer detection, but also the ability to use sequences for guiding biopsies and therapy (Figure 139.1). In addition, the high signal derived from modern MRI units can enable high-quality scans to be obtained without an endorectal coil, which is considered important for the widespread use of prostate MRI. Regardless of whether an endorectal coil is needed or not, obtaining multiple parameters during the MRI improves the sensitivity and specificity of the scan. In this section the four basic parameters comprising a complete mpMRI will be discussed.

### T2-weighted magnetic resonance imaging

T2-weighted (T2W) MRI of the prostate is the backbone of mpMRI for lesion detection and local staging. It is best for clear delineation of prostatic zonal anatomy and visualization of surrounding structures, with superior soft tissue contrast [5–7].

PCa can be visualized as a hypointense focus on T2W MRI due to loss of normal glandular morphology. However, low T2 signal intensity in the prostate is not always indicative of PCa. Benign conditions such as prostatitis, benign prostatic hypertrophy (BPH), scars, or posttreatment changes (e.g. radiation, hormone ablation) may have a similar appearance [8, 9]. Post-biopsy hemorrhage can also appear hypointense on T2W scans,

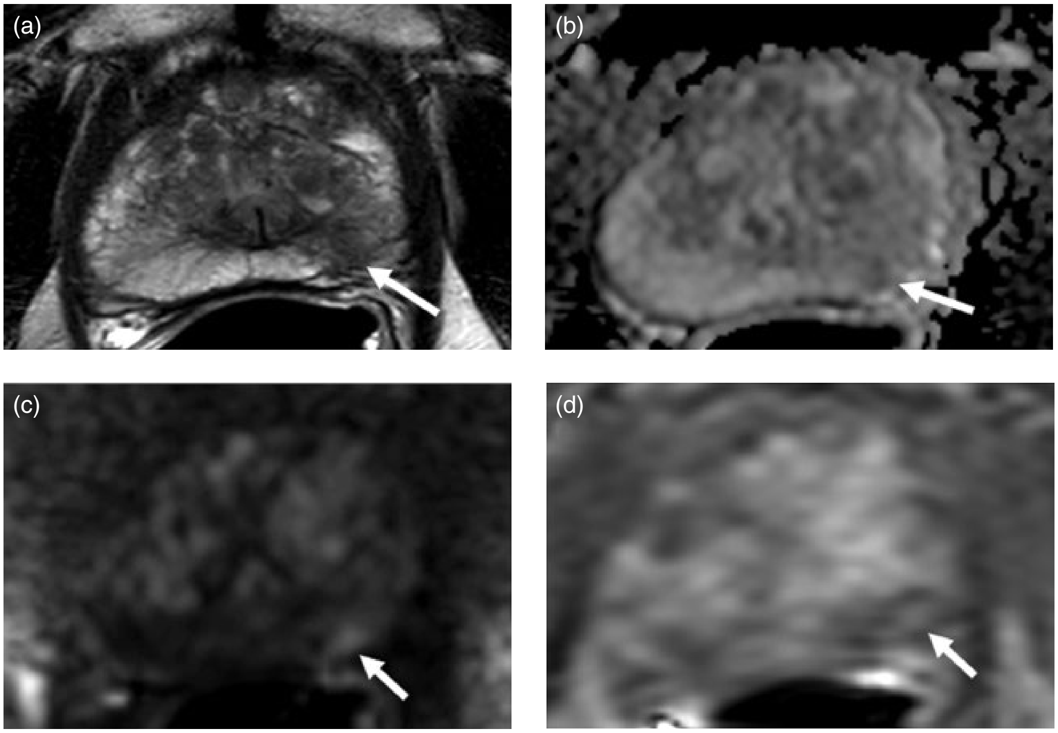

**Figure 139.1** A 67-year-old presented with PSA 4.67 ng/ml and underwent multiparametric MRI (mpMRI), which revealed PI-RADS v2 score 4 lesion in the left apical peripheral zone (arrows). Lesion was identified on T2-weighted MRI (a), apparent diffusion coefficient map of diffusion-weighted (DW) MRI (b), *b*-2000 image of DW MRI (c), and dynamic contrast-enhanced MRI (d). Subsequent transrectal ultrasound/MRI fusion-guided biopsy revealed Gleason 3+3 in 20% of biopsy core. Patient was offered active surveillance option with yearly monitoring using mpMRI and biopsy.

but is more easily distinguishable, as areas with hemorrhage correspond to hyperintense regions on T1-weighted MRI. Detection of PCa in the peripheral zone (PZ) is easier than it is in the transition zone (TZ). In the PZ, most PCa are hypointense against a background of high T2 signal intensity of the normal tissue. In the TZ, tumor is more difficult to differentiate because of the coexistence of BPH. Indicators of tumor in the TZ include homogeneous low to intermediate T2 signal intensity without a distinct capsule, ill-defined margins, and lenticular shape [6, 10].

T2W MRI can also be utilized for local staging. Extraprostatic extension (EPE) usually appears as a direct extension of the tumor out of the edge of the gland into surrounding hyperintense periprostatic fat. In most cases, EPE is subtle; secondary findings including asymmetry of the neurovascular bundle, tumor surrounding the neurovascular bundle, gland border irregularity or asymmetry, a relatively long contact of the tumor with the capsule, and obliteration of the rectoprostatic angle can be used to suggest EPE. If EPE is present, the patient is upstaged to T3a and this alters the treatment to a more aggressive approach [11]. Another part of staging is evaluating for seminal vesicle invasion (SVI), which is considered T3b disease. SVI can be seen as a low signal defect within the normally high-signal seminal vesicles. Two types of SVI are described: one is a direct extension of the tumor from its origin in the base of the prostate and the other is multifocal low signal intensity within the seminal vesicles not in continuity with the primary tumor. The presence of SVI upstages to T3b, and also affects subsequent treatment decisions [11] and likelihood of recurrence. Therefore, T2W MRI evaluation of EPE and SVI provides information regarding a patient's PCa that is vital to treatment planning.

T2W MRI has a wide range of sensitivities and specificities for detecting PCa (reported sensitivities: 27–100%; reported specificities 32–99%) as well as for staging (reported sensitivities 14–100%; reported specificities 67–100%). This range of performance in detection may be affected by significant variability of studied patient populations, as well as differences in the gold standard used (biopsy vs. surgery). T2W detection ability also depends on the sophistication of the MRI unit, experience of its operator, and experience of the reader. A large disadvantage of T2W MRI for accurate detection is that it is highly dependent on patient cooperation in order to minimize movement, and on the experience of the radiologist in subjectively determining signal differentiation [4]. However, even in ideal conditions, T2W MRI is not specific, and has demonstrated limited ability to diagnose PCa as a standalone method. A recent study from a top-rank institution demonstrated that T2W MRI alone at 3 T field strength revealed a detection accuracy of 80–90% for tumor foci larger than 1.0 cm in diameter [12]. However, for smaller tumors T2W MRI was far less accurate [13]. Nevertheless, for local staging, T2W is considered the most useful technique. The sequence is particularly useful for identifying EPE of a suspicious lesion. Bloch et al. evaluated the role of T2W MRI and dynamic contrast-enhanced (DCE) MRI in staging of PCa in a cohort of 108 patients and found an overall sensitivity, specificity, positive predictive value and negative predictive value for EPE of 75%, 92%, 79%, and 91%, respectively. In addition, for less experienced, moderately experienced, and highly experienced readers, they reported diagnostic accuracies for overall staging of 86%, 80%, and 91%, respectively, indicating that local staging based on these parameters is relatively easy to teach [14]. Staging using SVI identification on T2W images has proven successful as well. In a cohort of 573 patients of whom 28 had SVI, T2W MRI outscored all clinicopathologic variables in correctly predicting the SVI with an area under the curve (AUC) of 0.76 (vs. 0.62–0.73 for clinicopathologic variables) [15]. T2W combined with DCE MRI and diffusion-weighted (DW) MRI is even better, as unilateral atrophy, or calculi or clot within the seminal vesicles may mimic the appearance of SVI on T2 (Figure 139.2).

Although it is the backbone of mpMRI, T2W MRI is nonspecific; its use in combination with functional MRI can increase the accuracy of PCa detection and will be discussed next.

## Diffusion-weighted magnetic resonance imaging

DW MRI measures the random motion of water molecules within the tumor [16, 17]. Specifically, it measures water proton diffusion by utilizing apparent diffusion coefficient (ADC) [18]. Since this property is influenced by cellular density, membrane permeability, and extracellular space volume, DW MRI has the potential to explore several aspects of tissue microscopy [19, 20].

The basis of DW MRI is that stationary water protons will not acquire a phase shift when an external magnetic gradient is applied. Moving water protons, on the other hand, will acquire a phase shift proportional to the amount of motion, resulting in loss of signal. If this process is repeated for sequentially stronger external magnetic gradients (“*b*”-values), an estimate of the bulk water diffusion can be made with ADC values and represented on a voxel-by-voxel basis in the form of an ADC map [16]. Although the connection between random motion of water molecules and MRI was established many years ago, application of this principle to clinical imaging has only recently become feasible due to improved susceptibility artifact suppression [16]. First used for brain imaging in stroke, DW MRI has expanded its application to virtually every part of the body for oncology imaging, including the prostate [21, 22]. Cancers have significantly restricted water diffusion, which appears as a hypointense signal relative to surrounding tissue on ADC maps. This is due to cancer cells’ higher nuclear:cytoplasmic ratio, higher cellular density, and extracellular disorganization, which all contribute to trapping water more readily [21].

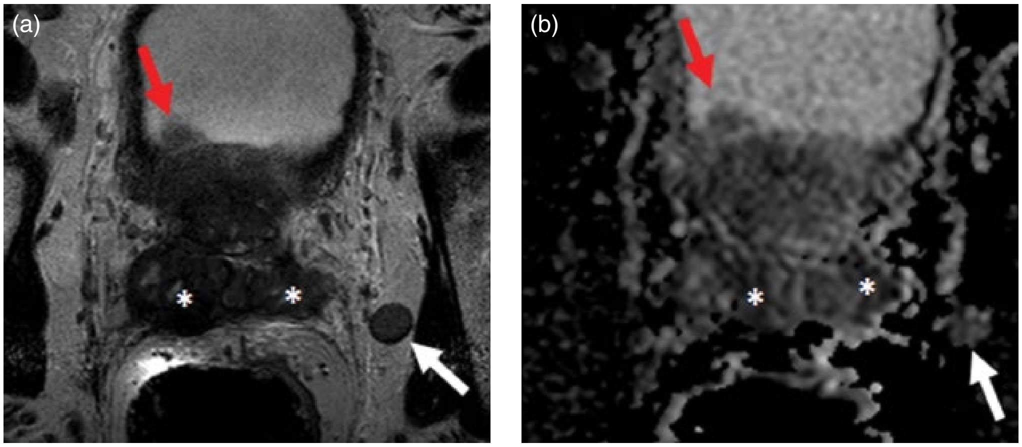

**Figure 139.2** A 66-year-old with serum PSA 48.90 ng/ml, diagnosed with Gleason 4+5 disease in the prostate base on TRUS/MRI fusion-guided biopsy. Multiparametric MRI exam was further evaluated for staging purposes, with axial T2-weighted MRI (a) showing evidence of seminal vesicle invasion (asterisks), bladder wall invasion (red arrow), and left iliac chain adenopathy (white arrow). These findings are further verified by apparent diffusion coefficient map of diffusion-weighted MRI (b).

DW MRI is obtained at various *b*-values ranging from 0 to 800 s/mm$^3$, which are postprocessed to create the ADC values that contribute to the final ADC map [23]. At *b*-values >1000 s/mm$^3$, a "high *b*-value" image can be produced [24]. This sequence displays as almost the inverse of the ADC map: areas with more diffusion restriction appear as hyperintense on the high *b*-value images, which are "raw" images and not processed. Therefore, tumors in the prostate appear as focal areas of hyperintensity relative to the surrounding tissue on high *b*-value sequences while on ADC maps the same areas appear focally hypointense. In general, high *b*-value DW MRI tend to have lower signal and therefore lower resolution, so suspicious areas should correspond to findings on other sequences of the mpMRI for more accurate detection. The high *b*-value images can either be directly acquired at higher magnetic gradient or calculated from lower *b*-value images using different decay models [25]. It has been shown that *b*-values >1500 s/mm$^3$ are best for maximizing lesion visibility for PCa detection on mpMRI [26]. With optimal high *b*-value imaging, sensitivities ranging from 78% to 94% have been reported. However, *b*-values >2500 s/mm$^3$ should not be used, as there is too great a compromise in signal-to-noise ratio in this range [27].

Advantages of DW MRI compared with other MRI techniques include DW imaging's short acquisition time and relatively high sensitivity and specificity for cancer [19]. DW MRI may also yield qualitative and quantitative information for predicting locally recurrent PCa post-therapy [28]. Active tumors tend to have lower ADCs while tumors undergoing therapy are observed to have progressively higher ADCs. In addition to enabling good detection and therapy monitoring, DW MRI could also play a role in active surveillance [16]. However, DW MRI has some limitations such as low spatial resolution, which hinders local staging. It is also prone to susceptibility artifacts, especially caused by rectal gas. Moreover, DW MRI findings of the TZ are more challenging as TZ is more heterogeneous due to BPH [29, 30]. TZ tumors and PZ tumors should have the same appearance on high *b*-value sequences and ADC maps. Based on diffusion signal alone, such lesions can be confusing; however, when they are placed in the anatomic context of a well-circumscribed BPH nodule, as seen on T2W MRI, it becomes easier to differentiate potential malignancy from benign tissue. DW MRI can also be falsely positive due to hemorrhage, prostatitis, dysplasia, and high-grade prostatic intraepithelial neoplasia, as well as posttreatment changes. In a study of 49 patients who underwent radical prostatectomy following MRI, Oto et al. analyzed the diffusion parameters of TZ PCa, stromal hyperplasia (SH), and glandular hyperplasia (GH) in the differentiation of TZ cancers from benign hyperplasia. Thirty-eight foci of carcinoma, 38 SH nodules, and 38 GH nodules in the TZ were localized on the basis of histopathologic correlation. Receiver operating characteristic (ROC) and multivariate logistic regression analyses were performed for the differentiation of TZ cancers from hyperplastic foci. They found the average ADCs as 1.05, 1.27, and 1.73, respectively, in TZ cancers, SH foci, and GH foci yielding AUCs of 0.99 and 0.78, respectively, for differentiation of carcinoma from GH and SH [29]. Thus, it may be possible to differentiate tumors from BPH nodules on the basis of their ADC value.

The addition of DW MRI to standard imaging protocols dramatically improves the overall diagnostic efficacy of MRI for PCa detection and for tumor recurrence [31]. For instance, Morgan et al. demonstrated a 93.8% sensitivity and 75% specificity, and AUC up to 0.992 for lesions >0.4 cm$^2$ when DW MRI was added to T2W MRI in the detection of local prostate tumor recurrence [17]. This is in contrast to T2-only detection of prostate tumor recurrence, reported with AUC of 0.67 by Petraki and Sfikas [32]. In a meta-analysis of 19 recent articles conducted by Tan et al., DW MRI both increased sensitivity and increased specificity for PCa detection compared to T2W MRI alone [19]. Rosenkrantz et al. studied 51 patients and showed that DW MRI and ADC maps had a greater sensitivity than T2W MRI for less experienced readers and that they improved detection of PZ lesions that were difficult to recognize on T2W MRI [33].

DW MRI may provide some additional information about the nature of the tumor detected as well. Studies have shown that in PCa, ADC values inversely correlate with lesion Gleason score on histopathology and can therefore play a role in risk stratification [34–36]. Hambrock et al. reported a negative correlation between the median ADC in the tumors and the PZ tumor Gleason grade in 51 patients [35]. Turkbey et al. found a similar negative correlation between tumor ADC values and Gleason scores in 48 patients scanned at 3 T. Moreover, they reported utility of ADC values in predicting D'Amico clinical risk scores [36]. The ability to predict tumor aggressiveness could be useful in selecting appropriate therapies. Thus, DW MRI is so far the most promising quantitative MRI technique for noninvasively accomplishing this. However, there remains overlap between Gleason scores and ADC values, thus limiting its predictive value in individual patients. Moreover, not all lesions found to have low ADC values are actually tumors. This underscores the need to obtain biopsies in patients with suspected lesions on MRI regardless of their ADC value.

## Magnetic resonance spectroscopic imaging

Proton MR spectroscopic imaging (MRSI) is a functional method capable of assessing prostate tissue metabolism. MRSI used to be more commonly included in mpMRI, but has recently fallen out of favor since its additive value is limited. Each volume of interest (voxel), acquired in a three-dimensional (3D) MRS image, contains a metabolite spectra. The spectra demonstrates the relative concentrations of the specific tissue metabolites citrate (Cit), creatine (Cr), and choline (Cho). Prostate tumors are characterized by increased levels of choline and decreased levels of citrate, whereas normal prostate tissues contain high levels of citrate and relatively low levels of choline and creatine. This allows for differentiation between the tissues with MRSI, and increases in ratios (Cho + Cr)/Cit and Cho/Cit serve as markers for likely PCa. The metabolic differences are likely secondary to increased cell membrane turnover, which results in high choline levels in prostate tumors, and abnormal functioning of tumor cells leading to low levels of citrate. Once the ratios are determined, a scoring method for metabolic ratios is used to characterize the tumor [37].

Metabolism is a unique measure in tumor detection. Several investigators have noted a correlation between metabolic ratios (e.g. Cho/Cit) and PCa aggressiveness [5, 38–41]. Kobus and colleagues studied the performance of MRSI alone and in combination with ADCs of DW MRI at 3 T. In this study, 54 patients with biopsy-proven cancer underwent MRSI prior to prostatectomy. They found significant correlation between pathology classification of tumor aggressiveness and (Cho + Cr)/Cit ratio, Cho/Cit ratio, and ADC values in PZ tumors (areas under the curve of 71%, 67%, and 81%, respectively). They also found significant correlation with (Cho + Cr)/Cit ratio and Cho/Cit ratio in the TZ (rho = 0.58 and rho = 0.60, respectively). Although further validation is needed, MRSI has the potential to be useful in assessment of tumor aggressiveness [42]. This is particularly useful as emphasis is placed on differentiating clinically significant tumors from lower grade tumors that may have no impact on the patient's longevity [43]. Multiple authors have incorporated MRSI into nomograms to help predict the aggressiveness of tumors [44, 45]. As an example, Shukla-Dave et al. studied 181 PCa patients using nomograms incorporating MRSI and nomograms based on clinical data alone. They found that when MRSI results used to distinguish low- and high-risk cancers were incorporated into nomograms, these predictions performed significantly better ($P \leq 0.05$) [44].

A prospective multicenter study performed by the American College of Radiology Imaging Network (ACRIN) to determine the benefit of combined endorectal MRI and MRSI concluded that T2W MRI alone and combined T2W MRI–MRSI had similar accuracy in PZ cancer localization (AUC, 0.60 vs. 0.58, respectively; $P > 0.05$). AUCs for individual readers were 0.57–0.63 for T2W MRI alone and 0.54–0.61 for combined T2W MRI–MRSI without significant difference [46]. On the other hand, in a recent study by Selnaes et al., the authors used a stringent segmental matching of histopathology and MRI. They found that combination of T2WI and MRSI had an AUC of 0.90, which was better than T2WI alone with an AUC of 0.85 [47].

MRSI has its limitations. It is technically challenging and time consuming, and adds to the expense of MRI studies. The spectrum is subject to artifacts. MRSI requires additional time for acquisition and separate postprocessing, decreasing clinical throughput and requiring skilled labor. Most vendors now supply a workable MRSI package for prostate imaging, but proper performance of the scan is still needed. For instance, proper MR shimming is needed to accentuate key peaks and suppress water, and lipid contamination to produce quality spectra. This often necessitates an onsite physicist. If the scan can be obtained, there are then challenges in interpretation. The large size of the MRSI voxel may cause partial volume effects, which can cause the image to be misread. Due to many of these limitations, MRSI has not gained the widespread popularity in clinical use that other mpMRI sequences have achieved. Currently, MRSI has largely been dropped from MRI protocols at most centers.

## Dynamic contrast-enhanced magnetic resonance imaging

DCE MRI is an important functional sequence of mpMRI. In DCE MRI, fast T1-weighted sequences are acquired before, during, and after the intravenous injection of an MRI contrast agent (such as low molecular weight gadolinium chelates). The rapid sequences are used to detect the arrival and uptake of the contrast into the prostate before washing out of the gland. This uptake provides a rough delineation of perfusion in the prostate, which can suggest regions of hypervascularity [48, 49]. Tumors are often hypervascular and enhance earlier and with more rapid wash-out than normal tissue. This is due to neoangiogenesis, a property of tumors that leads to rapid vessel growth and increased vascular permeability. Neoangiogenesis is thought to be related to tumor aggressiveness [50]. Usually, tumor foci within the prostate gland in the PZ tend to enhance earlier, faster, and to a greater extent than normal tissue and other benign conditions. Tumors also display a characteristic early contrast wash-out compared with healthy prostate. However, in the TZ, these abnormal enhancement patterns can also be seen in BPH nodules and inflammation, making assessment and detection of tumor more difficult [51]. In both prostate zones, smaller and low-grade tumor foci frequently do not demonstrate abnormal enhancement on DCE MRI [48, 52].

The most common evaluation method for DCE MRI is the qualitative approach, in which focal early and intense enhancement with early wash-out compared to normal prostatic tissue is visually detected. More quantitative approaches can be used as well. Pharmacokinetic parameters can be determined semi-quantitatively using different kinetic models which provide indices of vascular permeability. The most commonly used quantitative parameters based on a modified Toft's model are $K^{\mathrm{trans}}$ (transfer of gadolinium contrast from the vascular compartment to the tumor compartment representing forward vascular permeability and flow), $k_{\mathrm{ep}}$ (reverse transfer of contrast from the extracellular space back to the plasma space representing backward leakage) [53]. Higher grade tumors tend to have higher $K^{\mathrm{trans}}$ and $k_{\mathrm{ep}}$ parameters compared with normal surrounding prostate tissue. However, smaller and low-grade tumors often do not demonstrate abnormal enhancement on DCE MRI [52]. This information can be helpful to predict more aggressive disease and thus manage patients more appropriately. Additional semi-quantitative analysis can be based on fitting the time–gadolinium concentration curve to the two-compartment model. In addition to the calculated permeability parameters, the time–gadolinium concentration curve can be used to measure the AUC, time to peak enhancement, and initial slope. These enhancement curves can be classified into one of three types: type 1 persistent increase; type 2 plateau curve; and type 3 decline after initial upslope. Often, mixtures of different curves are found within lesions, but of these curves, type 3 is most commonly associated with PCa [54].

DCE MRI has high sensitivity, which can be useful for initial evaluation of potential tumor foci and has been routinely used to detect lesions, cancer aggressiveness, and monitor therapeutic response in clinic trial settings. The modality alone has a sensitivity and specificity range of 46% to 96% and 74% to 96%, respectively; as always, these ranges are highly dependent on patient selection, image acquisition and analysis technique, lesion size and diagnostic criteria [4]. A recent work by Puech et al. analyzed the performance of DCE MRI at 1.5 T in identifying and localizing intraprostatic cancer foci in relation to cancer volume at histology. The sensitivity and specificity of DCE MRI for identification of tumor foci of any volume were 32% and 95%, respectively. For identification of tumor foci >0.5 ml, the sensitivity and specificity were 86% and 94%, respectively, and the AUC was 0.874 [55]. Combining DCE MRI and T2W MRI resulted in a significant improvement of diagnostic accuracy of tumor detection up to 91% in 34 patients [56].

There are limitations in the performance of DCE MRI that should be considered. For instance, the TZ is a challenging area for tumor detection since a significant overlap is present between DCE MRI features of BPH and PCa. Therefore, previously published works on DCE MRI performance in the TZ are controversial. Some results have suggested potential usefulness of DCE in the TZ [57], while other studies failed to do so [58]. DCE MRI used with other pulse sequences for further anatomical and functional information can yield improved results for tumor detection in the TZ. In addition, staging accuracy and detection of EPE and SVI requires high spatial resolution for anatomic differentiation, which is why the use of combined endorectal/body phased array coils is needed. DCE MRI alone still suffers from relatively lower spatial resolution. It still can offer utility in identifying EPE and SVI; DCE MRI combined with a higher resolution pulse sequence such as T2W MRI is required to improve PCa detection and local staging. Bloch et al. found AUC 95% overall staging accuracy when DCE MRI was combined with T2W, up to a 3% and 11% AUC improvement compared with DCE MRI and T2W MRI alone, respectively [59, 60]. DCE MRI can play a role in staging to confirm suspicion of SVI detected via T2W MRI and/or DW MRI. Presence of an early enhancement within a seminal vesicle lesion can be meaningful for confirmation of invasion. Ogura et al. interpreted early enhancement within SVs at DCE MRI and reported that this finding has accuracy rates as high as 97% for SVI in a cohort of 38 patients [61].

## Interpretation of multiparametric MRI

Traditionally, interpretation of mpMRI has been quite subjective, with readers using signal findings to identify suspicious areas in the prostate. Different scoring systems for identifying lesions were utilized at each institution. As the role of MRI has continued to grow in PCa diagnosis and management, steps have been taken towards creating a standardized method of image interpretation. In 2015, the Prostate Imaging-Reporting And Data System version 2 (PI-RADS v2) was released as part of this effort. PI-RADS v2 is a set of guidelines that includes standardized imaging parameters for sequence acquisition as well as the PI-RADS v2 scoring system. The mpMRI sequences accounted for in PI-RADS v2 are multiplanar T2W MRI, DW MRI (ADC map and high $b$-value images ($b \geq 1500\,\mathrm{s/mm^3}$)), and DCE MRI with rapid acquisition of T1 images before, during, and after contrast administration. The scoring system utilizes characteristic signal patterns on mpMRI indicative of malignancy in the PZ and in the TZ [62].

Each sequence of mpMRI (T2W MRI, DW MRI, DCE MRI) receives its own score for each identified suspicious lesion. T2W MRI and DW MRI are scored on a scale of 1 to 5, while DCE MRI is recorded as positive or negative for enhancement. Each lesion is then given an overall score scaled 1 to 5, mostly influenced by what zone of the prostate the lesion is found in. In the PZ, DW MRI serves as the dominant sequence. This means that the score of DW MRI is considered first, and for scores 1, 2, 4, and 5, this serves as the overall score as well. If a PZ lesion is given DW MRI score of 3, the overall score can be upgraded to 4 if the lesion is also DCE positive. In contrast, in the TZ, T2W MRI serves as the dominant sequence. T2W MRI scores 1, 2, 4, and 5 serve as overall lesion score; T2W MRI score 3 can be upgraded to an overall score 4 if the TZ lesion of interest is given a DW MRI score of 5.

Overall PI-RADS v2 scores suggest probability of clinically significant cancer to be present in an identified lesion on imaging. Score 1 suggests very low probability, score 2 indicates low probability, score 3 indicates intermediate probability, score 4 indicates high probability, and score 5 indicates very high probability. Scoring determination for each sequence is based on signal findings consistent with tumor as described previously in this chapter. For T2W MRI scoring, heterogeneous or hypointense signal intensity can be suspicious in both the PZ and TZ. Heterogeneous signal intensity with obscured margins corresponds with a T2W MRI score of 3, while a circumscribed and homogeneous hypointensity corresponds with score 4 if it measures <1.5 cm in diameter, and score 5 if it measures >1.5 cm and/or shows suggestion of EPE. In DW MRI, the ADC map and high *b*-value sequence are evaluated together. For DW MRI score 3, a focal mildly or moderately hypointense area can be seen on ADC that corresponds with an isointense or mildly hyperintense area on the high *b*-value image. For DW MRI score 4, a focal markedly hypointense area on the ADC map and corresponding markedly hyperintense area on high *b*-value can be seen for a lesion <1.5 cm in greatest diameter; for score 5, the dimension of the lesion is >1.5 cm and/or there is indication of EPE. Finally, DCE MRI is positive if an area in the prostate focally enhances earlier than or synchronous with enhancement of adjacent tissue, and corresponds to a suspicious area on the other sequences of mpMRI. DCE MRI has the potential to upgrade the overall score of a PZ lesion scored 3 on DW MRI, but otherwise does not change overall scoring of lesions. Absence of early enhancement does not eliminate the potential of clinically significant cancer in a suspicious lesion found on other sequences. However, DCE MRI should be included in all mpMRI exams, as careful evaluation can help identify smaller foci of clinically significant cancer [62] (Figure 139.3).

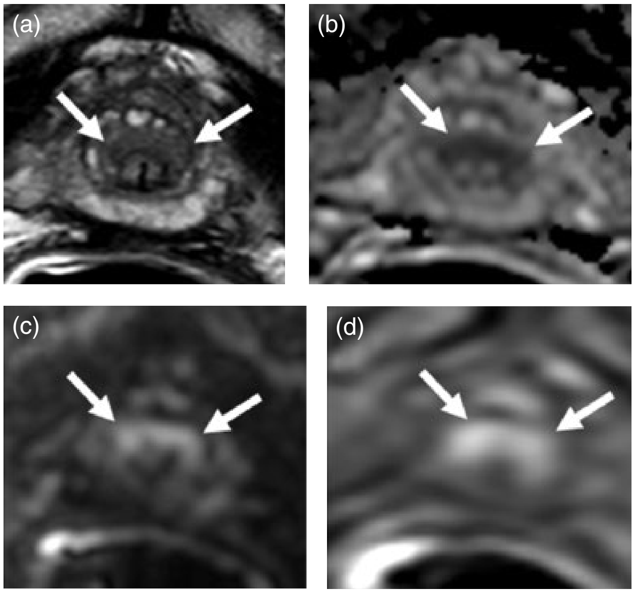

**Figure 139.3** A 75-year-old (serum PSA 14.60 ng/mL) with score 4 lesion identifed in the midline apical anterior transition zone on multiparametric MRI according to PI-RADS v2 criteria. This lesion was visualized as a uniformly hypointense area (arrows) measuring <1.5 cm on T2-weighted MRI (a), with a corresponding hypointensity (arrows) on the apparent diffusion coefficient map of diffusion-weighted (DW) MRI (b), a matching hyperintensity (arrows) on *b*-2000 DW MRI (c), and early enhancement (arrows) on dynamic contrast-enhanced (DCE) MRI (d). This TZ lesion received a PI-RADS v2 score 4 on T2-weighted MRI and DW MRI, and a positive score on DCE MRI. Patient underwent subsequent TRUS/MRI fusion-guided biopsy, yielding Gleason 3+4 prostate cancer diagnosis.

Since its introduction, many institutions have adopted PI-RADS v2 as the method of interpretation of their prostate mpMRI exams. However, while PI-RADS v2 is a large step towards standardization, it is still not optimal and there is variability among readers. In a multireader analysis, average sensitivity for lesion detection across five readers was 63%, with interreader agreement of 58%. This variability is also present in index lesion interpretation, with interreader agreement of 86% [63]. As PI-RADS v2 is based on expert opinion, complete validation of the system remains to be investigated.

## Use of multiparametric MRI for biopsy guidance

mpMRI is increasingly being used for identification of suspicious lesions. However, the mpMRI interpretation alone has little diagnostic value for a PCa patient. Only after the mpMRI findings are used to obtain a tissue diagnosis can a proper plan be implemented for patient management.

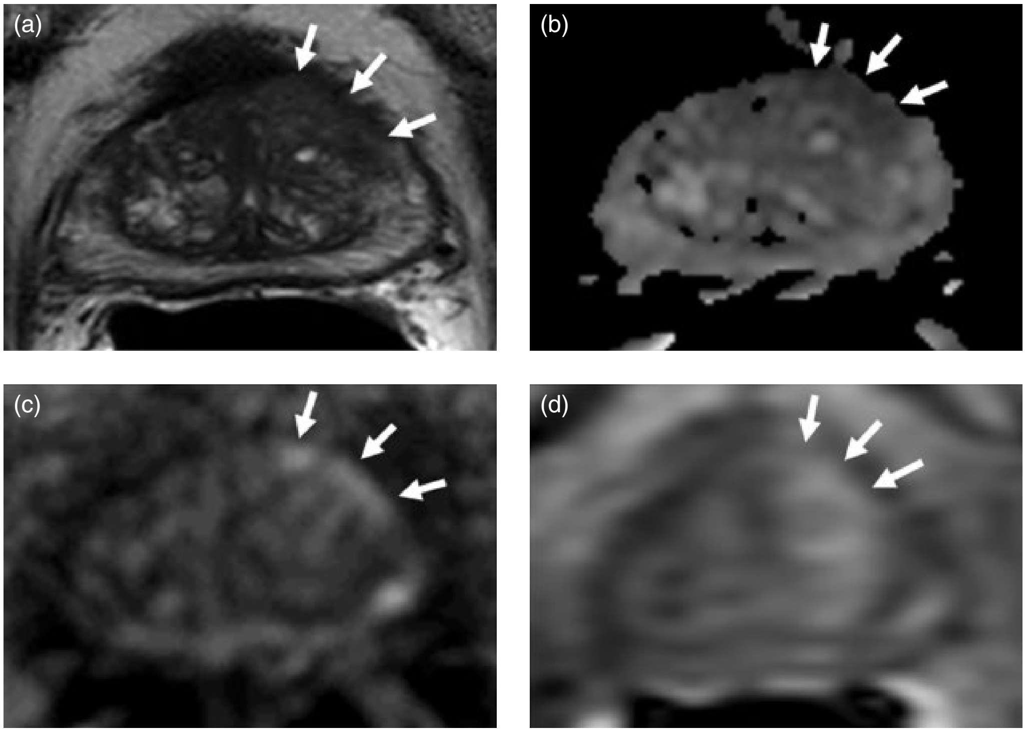

**Figure 139.4** A 67-year-old who presented in 2009 with initial PSA 5.90 ng/ml, and has had subsequent PSA measurements and negative systematic biopsies over the past 7 years. Patient had his first multiparametric MRI in 2016 which revealed a PI-RADS v2 score 5 lesion (1.6 cm) in the left mid anterior transition zone (arrows) shown on T2-weighted MRI (a), apparent diffusion coefficient map of diffusion-weighted (DW) MRI (b), *b*-2000 image of DW MRI (c), and dynamic contrast-enhanced MRI (d). TRUS/MRI fusion-guided biopsy yielded Gleason 3+4 prostate cancer. Following these new results, the patient was offered active management.

Traditionally, the standard of tissue diagnosis has been a 12-core systematic biopsy. However, the advent of TRUS/MRI fusion-guided biopsy has introduced targeted biopsy in PCa diagnosis. Common fusion systems include the UroNav, Artemis, Urostation, and BiopSee platforms. During the biopsy procedure, real-time ultrasound is fused with a previously acquired mpMRI to best target identified lesions. TRUS/MRI fusion-guided biopsy has been shown to increase detection of intermediate- and high-risk cancers, and decrease detection of low-risk cancers (Figure 139.4) [64–67]. For example, Siddiqui et al. demonstrated that tumors biopsied using mpMRI and subsequent fusion biopsy detect 30% more clinically significant cancers and 17% fewer insignificant cancers compared to traditional systematic biopsy [64].

## Conclusion

Accurate detection and local staging of PCa is important to deliver correct treatment approaches for patients. mpMRI can detect clinically relevant intraprostatic tumor foci and can provide valuable information about local staging and tumor aggressiveness. However, mpMRI is still a relatively recent addition to the PCa workup and its use is still controversial in some settings. As this modality migrates out into community practices it is important that attention is paid to issues of image quality, interpretation quality, adherence to international reporting standards (e.g. PI-RADS v2) and the quality of MRI/TRUS fusion-guided biopsy if this method is to provide uniformly positive benefits across all patients with PCa.

## Introduction

Benign prostatic hyperplasia (BPH) is an age-dependent pathoanatomic condition with an initial histopathologic development after 40 years of age, and prevalence rates of approximately 50% and 90% by 60 and 85 years of age, respectively. Cell proliferation associated with BPH is composed of both epithelial and stromal elements and may result in benign prostatic enlargement (BPE), bladder outlet obstruction (BOO), and a constellation of lower urinary tract symptoms (LUTS) that are commonly classified as voiding or storage symptoms.

In most instances, the patient has more than one complaint. It has generally been assumed that voiding symptoms are caused by prostatic obstruction and that storage symptoms are caused by inflammation or detrusor overactivity. Despite the logic implied, most clinical studies that document the relationship between symptoms and underlying pathophysiology have established no such correlation.

Although existing medical and surgical interventions attempt to reduce the obstructive component to provide symptomatic relief, the association between BPH, benign prostatic obstruction (BPO), and BOO is complex. For example, it is unclear whether urethral obstruction is the primary mechanism by which BPH causes symptoms. Nor is it known whether the relief of the obstruction is a prerequisite to successful treatment of symptoms. Likewise, the relationship between symptoms and commonly used indices (to measure LUTS suggestive of prostatism), such as uroflow and postvoid residual (PVR) urine, is unknown.

Recent evidence suggests that the etiology of prostatic symptoms is multifactorial involving (i) prostatic urethral obstruction, (ii) impaired detrusor contractility, and (iii) detrusor overactivity [1]. The best method to definitively diagnose BOO is the detrusor pressure–uroflow flow study (PFS), but there is much more to be obtained from urodynamics than simply diagnosing obstruction.

This chapter describes existing urodynamic techniques used in the diagnosis of BPH, and reviews the role of urodynamics in the evaluation of LUTS and urinary incontinence.

## Background

LUTS are generally categorized into storage, voiding, and postmicturition symptoms [2]. Storage symptoms include daytime frequency, nocturia, urgency, and urinary incontinence. Voiding symptoms are composed of slow stream, splitting or spraying, hesitancy, intermittency, and straining to void. Postmicturition symptoms include feeling of incomplete emptying and postmicturition dribbling. In men, BOO associated with BPH is only one of many causes of LUTS. Other causes include overactive bladder (OAB), neurogenic bladder, impaired detrusor contractility, low bladder compliance, and polyuria. It is not possible to make the diagnosis of BOO on symptom assessment alone. In patients with LUTS and BPH, urodynamic evidence of BOO exists in only 50–66% of patients [3–6]. Furthermore, a number of studies have demonstrated a lack of correlation between symptoms, the American Urological Association (AUA) symptom score or the Danish Prostate Symptom Score, and urodynamic data in patients with suspected BPH and BOO [7–10].

Determining the urodynamic abnormalities responsible for LUTS is important so that treatment can be directed at the underlying pathophysiology. Currently,

| | iii) Bladder capacity |
| | iv) Voided volume |

the majority of medical and surgical interventions target the reduction or elimination of prostatic obstruction, yet only about two-thirds of men are actually obstructed according to urodynamic criteria. In fact, therapies should be specific for detrusor overactivity, urgency, and impaired detrusor contractility. Urodynamics are necessary to make the distinctions between these entities.

The most definitive method of diagnosing urethral obstruction and impaired detrusor contractility is the detrusor pressure–uroflow study, whereas only cystometry is necessary to assess urgency and detrusor overactivity. Although questionnaires, symptom analysis, uroflow, and postvoid residual urine volumes (PVR) all play a role in evaluating men with suspected BOO, only urodynamics can make the necessary distinctions to allow therapy to be tailored to the underlying condition.

## Defining and quantifying symptoms

Defining and quantifying symptoms are important for two reasons. First, there is an imperfect correlation between symptoms, symptom severity, bother, and underlying pathophysiology. It is therefore important to quantify each of these variables separately in order to tailor the treatment to the individual patient's wants and needs. Second, in order to evaluate treatment outcomes in any meaningful way, it is necessary to tabulate this data before and after treatment (Table 140.1). There are numerous LUTS questionnaires and patient-reported outcome instruments, but no single questionnaire contains all of the domains necessary to define and quantitate the necessary data for clinical care or outcomes research. In our judgment, the two best are the ICIQmale LUTS-SF and the Lower Urinary Tract Symptom Score (LUTSS) [11, 12]. The latter is divided into six subscores: voiding, storage, OAB, incontinence, nocturia, and bother. It is also available as a mobile app that can be completed remotely by the patient and displayed in a graphic format that allows visual comparison of treatment outcomes (Figure 140.1).

## Preparation for urodynamic study

The main purpose of urodynamic evaluation is to document the underlying cause of the patient's complaints and to correlate symptoms with urodynamic findings. From a clinical standpoint, the purpose of urodynamic testing is to measure and record various physiologic variables while

**Figure 140.1** Lower Urinary Tract Symptom Score (LUTSS) and bladder diary displayed via a mobile app. The patient is a 58-year-old man who presented with severe lower urinary tract symptoms. (a) Graphic representation of the LUTSS. The LUTSS is a 14-question questionnaire composed of six subscores: voiding symptoms, storage symptoms, overactive bladder (OAB), incontinence, nocturia, and LUTS bother. All scores are normalized on a scale of 0–100 (100 is the worst possible symptoms). The top graph in blue was competed prior to TURP; the bottom one in brown three months postop shows dramatic improvement in all scores. (b) Twenty-four-hour bladder diary pre and post TURP. Abnormal values are in red.

the patient is experiencing those symptoms that constitute his usual complaints. Thus, in this context, urodynamics should be considered to be a provocative test of vesicourethral function, and it is the responsibility of the examiner to ensure that the patient's symptoms are reproduced during the study. To this end, it is important that the examiner has all relevant clinical information prior to and during the urodynamic study. For example, the examiner should have results of fairly extensive evaluation including (i) a focused history (including symptom questionnaire), (ii) focused physical examination, (iii) urinalysis ± culture, (iv) a 24-hour bladder diary, (v) a 24-hour pad test (for patients with incontinence), (vi) uroflow, and (vii) PVR.

Furthermore, in order to interpret urodynamic studies more accurately, the following information should be available to the examiner before the start of the study:

- What symptoms are you trying to reproduce?
- What is the functional bladder capacity (maximum voided volume on the voiding diary)?
- What is the PVR?
- What is the uroflow? (Is there likelihood of either urethral obstruction or impaired detrusor contractility?)
- Is there a neurologic disorder that could cause neurogenic bladder?

The specifics of urodynamic techniques and parameters may confound the practicing physician, but in principle there are only five: cystometry, uroflow, leak point pressure, sphincter electromyography, and radiographic visualization of the lower urinary tract (if video is performed). Each technique may be performed alone or synchronously with one another. The tests are called multichannel urodynamics when done synchronously, and called video-urodynamics when performed with fluoroscopic visualization of the lower urinary tract. In the following section, use of each urodynamic technique in the evaluation of lower urinary tract symptoms will be explained.

## Evaluation of lower urinary tract symptoms

### Voiding symptoms with uroflowmetry

In general, voiding symptoms have one or more of three basic underlying etiologies: BOO, impaired or absent detrusor contractility, and/or trying to void when there is insufficient bladder volume. BOO is characterized by a detrusor contraction of adequate magnitude (pressure) and duration, and a diminished flow. Impaired contractility is characterized by a weak or poorly sustained detrusor contraction and a low flow. If a patient tries to void when there is an insufficient bladder volume, it may be difficult for him to initiate the stream and the flow is likely to be low because of the well-known correlation between bladder volume and urinary flow rate [13].

Uroflowmetry is a simple, objective, and noninvasive method to evaluate LUTS. Uroflowmetry is not used to evaluate filling symptoms. It should be performed in a private setting with the patient sitting or standing to reproduce normal voiding patterns. From simple uroflowmetry, the maximum urinary flow ($Q_{max}$), flow pattern, voided volume, and shape of flow curve can be obtained. After voiding, the PVR is recorded with ultrasound or catheterization if invasive urodynamics are to follow.

Uroflowmetry is best performed when the patient experiences a normal desire to void. A minimum urine volume of 150 ml provides an accurate study [13]. Existing nomograms provide values with age- and volume-adjusted flow rate [7, 8, 14]. A $Q_{max}$ of greater than 15 ml/s is considered normal, and approximately 95% of patients with this parameter will not be obstructed [15]. A $Q_{max}$ of less than 10 ml/s is considered abnormal, and of 10–15 ml/s is equivocal [15]. However, it should be noted that uroflowmetry cannot distinguish a low flow due to outlet obstruction from that due to impaired detrusor contractility [16]. A variety of normal uroflow tracings with normal curves and parameters are shown in Figure 140.2. Normal flow patterns have a bell-shaped curve, while patients with obstruction usually have a flattened curve. Interrupted flow patterns can be seen in patients with any of impaired bladder contractility, obstruction, or abdominal straining/voiding [17].

An equivocal uroflow may be seen in patients with significant obstruction and an abnormal flow may also be seen in those with poor detrusor function. It is obvious that BOO is usually accompanied by a low urinary flow rate, but a low flow may also be due to impaired detrusor contractility. In patients who are obstructed, uroflowmetry cannot differentiate between different types of urethral obstruction (BPH, urethral stricture, etc.). Figure 140.3 displays two similar abnormal uroflowmetry patterns despite their having different etiologies.

Despite these limitations, uroflowmetry remains a useful initial evaluation of men with LUTS. The AUA guidelines (2010; validated 2014) recommend uroflowmetry as an optional test in men with LUTS as initial diagnostic assessment or follow-up assessment after treatment. Ideally two flow rates should be obtained and each should have a voided volume of >150 ml [18]. However, the European Association of Urology Guidelines on BPH recommend uroflowmetry in the assessment and diagnostic workup of men with LUTS and it is considered mandatory prior to surgical intervention [19].

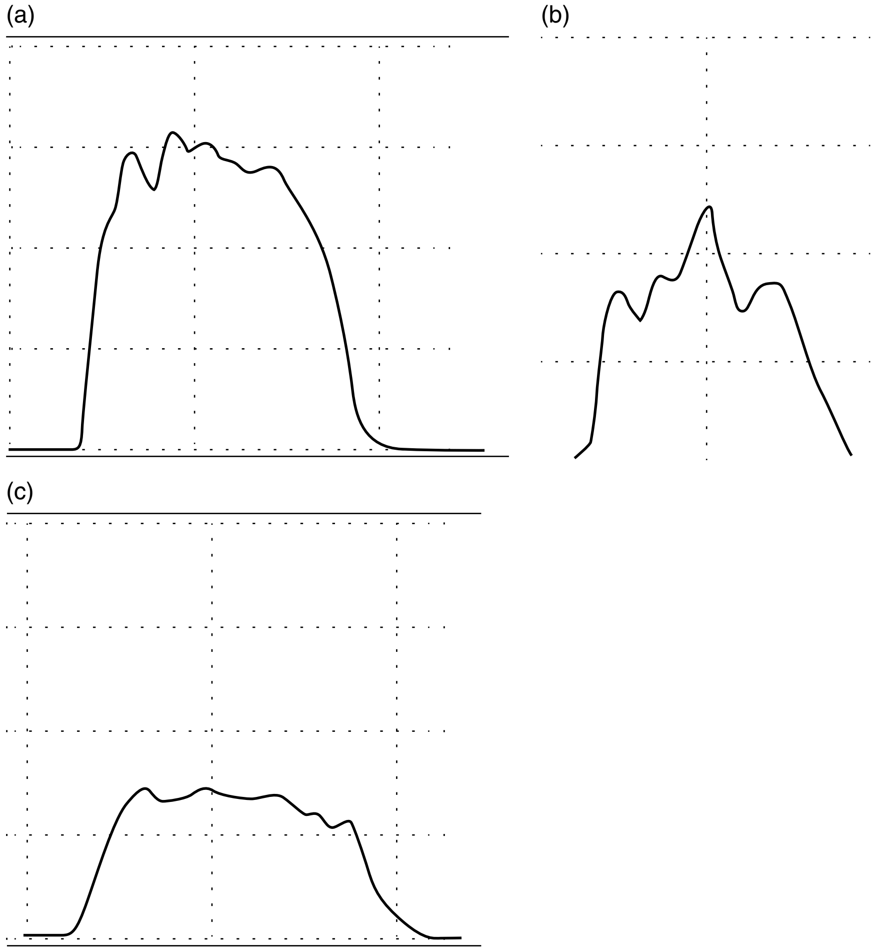

**Figure 140.2** Normal continuous uroflows. (a) Normal uroflow in a 52-year-old man. The pattern is continuous and the curve is very slightly fluctuating. Maximum flow ($Q_{max}$) = 31 ml/s; average flow rate ($Q_{ave}$) = 22 ml/s; voided volume = 269 ml; postvoid residual volume (PVR) = 0 ml. (b) Normal uroflow in a 53-year-old man. The pattern is continuous and the curve is fluctuating. $Q_{max}$ = 24 ml/s; $Q_{ave}$ = 13 ml/s; voided volume = 190 ml; PVR = 0 ml. (c) Normal uroflow in a 59-year-old man. The pattern is continuous and the curve is slightly fluctuating. $Q_{max}$ = 15 ml/s; $Q_{ave}$ = 10 ml/s; voided volume = 200 ml; PVR = 10 ml.

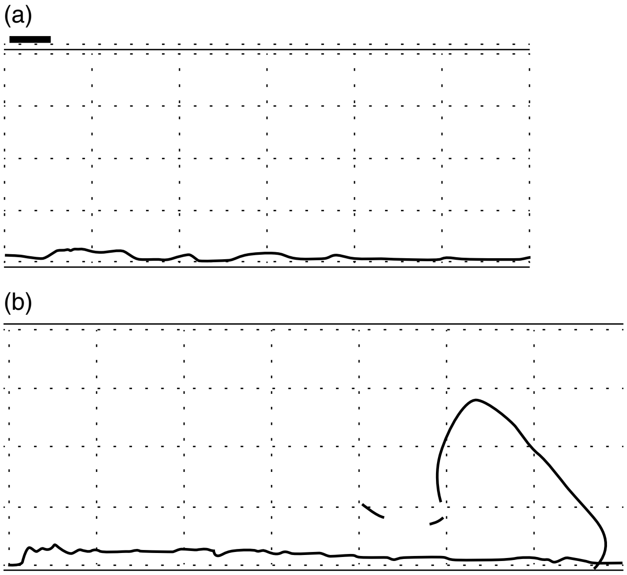

**Figure 140.3** (a) Low flow due to impaired detrusor contractility. Maximum flow ($Q_{max}$) = 2 ml/s; average flow ($Q_{ave}$) = 2 ml/s; voided volume = 58 ml; postvoid residual volume (PVR) = 120 ml. (b) Low flow due to urethral obstruction. $Q_{max}$ = 3 ml/s; $Q_{ave}$ = 2 ml/s; voided volume = 149 ml; PVR = 212 ml.

We recommend uroflow for all men as part of the diagnostic evaluation of LUTS and as an outcome measure when evaluating response to treatment.

## Filling symptoms with cystometry

Filling symptoms may be caused by detrusor overactivity, urgency, low bladder compliance, reduced bladder capacity, or polyuria. It is imperative to exclude other underlying causes of filling symptoms, such as urinary tract infection, bladder and prostate cancer, urolithiasis, and neurogenic bladder, prior to urodynamic testing. Polyuria can be caused by excessive fluid intake, diabetes mellitus, diabetes insipidus, and other less common conditions. Nocturia may be the result of abnormal drinking patterns, a reversal of the normal diurnal antidiuretic hormone cycle, congestive heart failure, venous insufficiency, sleep apnea, lower extremity edema, diabetes mellitus, or hypertension.

Filling cystometry is the only method that can document detrusor overactivity and low bladder compliance; however, it is not useful as a standalone procedure in men with LUTS. Currently, the AUA guidelines recommend

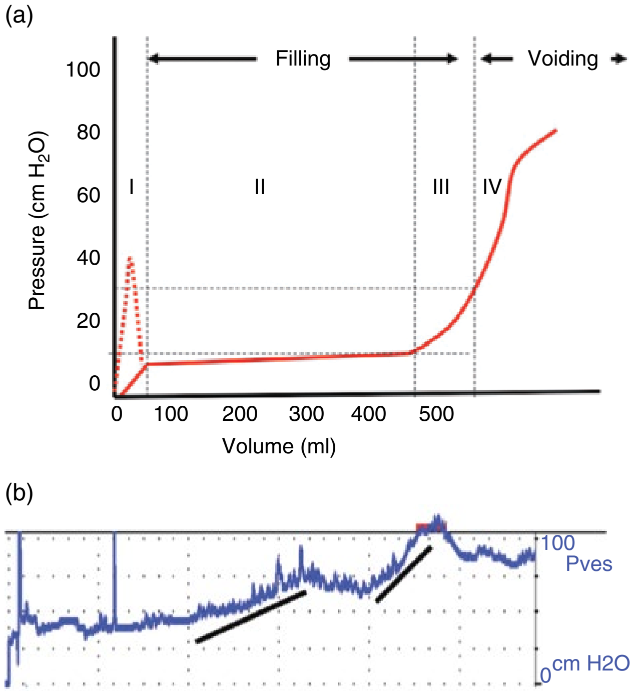

**Figure 140.4** (a) An idealized cystometrogram. The dashed red line in phase I is seen only with very rapid filling, such as that attained when $CO_2$ is used. It is attributed to the viscoelastic properties of the bladder wall. Note that bladder compliance changes at different bladder volumes. Bladder compliance during the tonus limb (phase II) = 400 ml/10 $cmH_2O$ = 40 ml/$cmH_2O$; at the end of phase III (500 ml) = 100 ml/20 $cmH_2O$ = 5 ml/$cmH_2O$. (b) This cystometrogram demonstrates two steep rises in vesical pressure ($P_{ves}$). The black lines parallel the pressure rises. Without further information, it is not possible to determine whether these are due to straining, detrusor contractions, or low bladder compliance.

that cystometry be done as part of the PFS. In men experiencing LUTS, up to two-thirds may be found to have detrusor overactivity. Despite poor physiologic explanation, resolution of detrusor overactivity can be expected in 50–70% of patients after outlet reduction [20, 21]. Figure 140.4 demonstrates an idealized cystometrogram as well as an actual cystometrogram from a patient: note that without abdominal pressure tracings, the cause of vesical pressure increase cannot be determined accurately.

## Multichannel urodynamics and video-urodynamics

The simultaneous measurement and display of multiple urodynamic parameters is the most precise diagnostic tool for evaluating abnormalities of micturition. As described earlier, the addition of radiographic visualization of the lower urinary tract with multichannel urodynamics is termed video-urodynamics. In these studies, radiographic contrast is used as the infusant for cystometry and other urodynamic parameters, including abdominal pressure, uroflow and sphincter electromyography, are recorded as well. By measuring multiple urodynamic variables, a better insight into the underlying pathophysiology is gained, as well as a better appreciation of their interrelationships and of artefacts. The International Continence Society has recommended standards for the performance of these studies [17, 22].

The main purpose of urodynamic evaluation is to recreate the patient's complaints and to correlate symptoms to the urodynamic findings. Thus, it is essential to understand the nature of a patient's complaints and to use the urodynamic evaluation as a provocative test to mimic those symptoms, as alluded to above. During the interactive process, the examiner should document whether or not the patient's symptoms are reproduced and, if they are, the underlying cause should be clearly understood before completion of the study.

## Urodynamic technique

A uroflow should be obtained prior to the urodynamic evaluation. Then, a 7 Fr double-lumen bladder catheter and rectal balloon catheter are passed into the bladder and rectum, respectively, to measure vesical and abdominal pressure. PVR is measured via the urethral catheter. Proper calibration is imperative to produce an accurate and clinically meaningful evaluation. Pressure transducers are zeroed to atmospheric pressure at the level of the symphysis pubis. Newer air-charged catheters have an air-filled balloon placed around a polyethylene catheter. Pressure measurements are made directly from the balloon to the air-filled catheter lumen and directly to the external pressure transducer; this conveniently eliminates the need for calibration to the symphysis pubis and flushing of the catheters, which was required in traditional fluid-filled systems. During calibration the patient should be asked to cough or Valsalva to ensure proper reading of instruments on the computer display. Vesical pressure ($P_{ves}$) and abdominal pressure ($P_{abd}$) are measured directly from the urethral and rectal catheters and displayed on a computer screen. Detrusor pressure ($P_{det}$) is electronically calculated by subtracting $P_{abd}$ from $P_{ves}$ and displayed on a third channel. Other channels display sphincter electromyelogram (EMG), infused bladder volume, filling rate, voided volume, and uroflow. For video-urodynamics, fluoroscopic images are sampled periodically as well as at times of events such as urgency and during voiding. Standard urodynamic parameters measured include bladder compliance ($C$ = change in bladder volume ($\Delta V$)/change in detrusor pressure ($\Delta P_{det}$)), maximum detrusor pressure, detrusor pressure at maximum flow ($P_{det}Q_{max}$), and bladder capacity. Bladder compliance should be measured with starting point at initiation of bladder filling and endpoint at either cystometric capacity or immediately prior to any detrusor contraction causing leakage based on International Continence Society (ICS) recommendations [2, 23]. Normal bladder compliance should be greater than 20 ml/$cmH_2O$, but there is no consensus on a strict value of normal or impaired compliance [23, 24]. The range in normal compliance is likely because compliance is highly dependent on bladder capacity. Impaired compliance is typically accepted as any value <20 ml/$cmH_2O$, but more importantly should be interpreted based on clinical context. The important components of urodynamic evaluation include presence of involuntary detrusor contractions, incontinence episodes, sphincteric coordination, and activity during storage and emptying, and bladder sensation. Bladder sensation is assessed at three standard points: volume at first sensation of bladder filling, first sensation of urgency, and strong sensation of urgency [23].

## Evaluation of filling symptoms

During bladder filling, the presence or absence of detrusor overactivity is noted and bladder compliance recorded. If detrusor overactivity is documented, the patient's awareness, concern, and ability to contract the sphincter, abort the stream, and prevent incontinence are noted. These characteristics are used to classify the type of overactive bladder [25] (Figure 140.5).

Detrusor overactivity is seen in over 50% of patients with BPH, but its presence does not correlate with urethral obstruction [1, 26–28]. A patient with clinical BPH may have detrusor overactivity in the presence of prostatic obstruction, but even in the absence of prostatic obstruction, detrusor overactivity may cause obstructive symptoms. For example, a patient may develop involuntary bladder contraction at a relatively low bladder volume, which is perceived as an urge to void. The patient rushes to the bathroom, however, by this time the involuntary contraction has subsided and there is no longer an urge to void. Attempts to void by the patient with straining and pushing will be unsuccessful due to the small bladder volume. Thus, once it has been determined that there are overactive detrusor contractions, it is important to determine the degree of the patient's awareness, concern, and control.

## Evaluation of voiding symptoms

BOO and urethral resistance are defined by PFS parameters. The BOO index (BOOI) is used to measure the degree of obstruction. It is calculated using the following formula:

$$\mathrm{BOOI} = P_{\mathrm{det}}Q_{\max} - 2Q_{\max}$$

where $P_{\mathrm{det}}Q_{\max}$ is the detrusor pressure at maximum flow. Men are classified as obstructed (BOOI >40), equivocally obstructed (BOOI >20–<40), or unobstructed (BOOI <20).

Multiple nomograms have been described to interpret PFS [15, 29, 30]. These plot detrusor pressure (at maximum flow) versus the maximum flow rate, and then divide results into unobstructed, obstructed, and equivocal categories. We prefer the Schafer nomogram because it provides a simple six-point obstruction scale: grade 0–1 is not obstructed, grade 2–3 is equivocal, and grade 4–6 is obstructed [22].

The urodynamic tracings, fluoroscopic images, and their application to a Schafer nomogram in Figures 140.6–140.8 demonstrate the role of each element in the differentiation of LUTS symptoms in three separate cases.

The Schafer nomogram also incorporates bladder contractility in addition to an obstructive index. The slopes of Schafer's contractility lines are obtained by the formula for bladder contractility index (BCI):

$$\mathrm{BCI} = P_{\mathrm{det}}Q_{\max} + 5Q_{\max}$$

A BCI greater than 150 is considered to be a strong contraction, a BCI less than 100 is considered to be weak, and a BCI of 100–150 is considered to be normal [31, 32]. However, for detrusor function to be normal, not only does it have to generate pressure, it also needs to sustain that pressure for long enough for the bladder to empty. Detrusor contraction duration (DCD) is a urodynamics parameter that is often overlooked and not well studied. Previous papers have defined it as "the bladder contraction in seconds from the first deflection from baseline during contraction until return to baseline detrusor pressure." Few studies have examined this parameter in men and even fewer in women. Kaplan et al. reviewed the urodynamic records of 120 consecutive patients (63 men and 57 women) who had moderate or severe AUA symptom score and found a weak correlation between DCD and BOO. DCD was longer in men with severe versus moderate AUASS (149.9 ± 62.3 vs. 109.3 ± 45.7 seconds) but this correlation was not seen in women [33]. This group also observed improved response to doxazosin in men with DCD >90 seconds [34]. Ameda et al. examined the urodynamic studies of 58 consecutive men with LUTS to assess the relationship between detrusor contraction duration, BOO, bladder capacity, detrusor contractility and symptoms to determine if DCD was a useful parameter for characterizing BOO [35]. In contrast to Kaplan et al.'s findings, this group did not observe a difference in DCD between patients with mild, moderate, and severe AUASS. Furthermore, there was no difference in DCD in patients who were obstructed versus those who were no obstructed (111.6 ± 53.7 seconds vs.

**Figure 140.5** (a) Urodynamic tracing of a type 2 overactive bladder and prostatic obstruction in a 53-year-old man with a 20-year history of refractory urgency, urge incontinence, and enuresis. During bladder filling the patient is instructed to neither void nor prevent micturition and to report his sensations to the examiner. There are a series of poorly sustained involuntary detrusor contractions (arrow) that he perceives as a severe urge to void, and then there is a sustained voiding contraction when he relaxes his sphincter and voids (blue oval). Detrusor pressure at maximum flow ($P_{det}$ at $Q_{max}$) = 100 cm$H_2O$; maximum flow ($Q_{max}$) = 8 ml/s (Schafer grade 5 obstruction). The bladder is filled again and there is another involuntary detrusor contraction. This time the patient is instructed to try to hold. He contracts his sphincter, obstructing the urethra, and the detrusor contraction subsides and he is not incontinent (yellow oval). (b) X-ray obtained at $Q_{max}$ shows a narrowed and faintly visualized prostatic urethra (arrows) characteristic of prostatic obstruction. The bladder is trabeculated and there are several small and medium-sized bladder diverticula. (c) X-ray obtained as the patient contracts his sphincter to prevent incontinence (gray oval). The contrast would be expected to stop at the distal prostatic urethra, but since the patient has prostatic obstruction that narrows the proximal urethra, no contrast is seen in the urethra at all.

91.5 ± 41.5 seconds). Our group measured DCD in 509 men and women who voided during urodynamics and observed that DCD tends to shorten with older age and that involuntary contractions are significantly shorter than voluntary contractions. (96.3 ± 41.7 vs. 63.4 ± 48 seconds). In addition, longer DCD was seen with higher detrusor pressure at maximum flow ($P_{det}$ at $Q_{max}$) and with higher maximum $P_{det}$ [36]. Further studies are needed to determine the role DCD plays in the mechanics of voiding and its clinical predictive value.

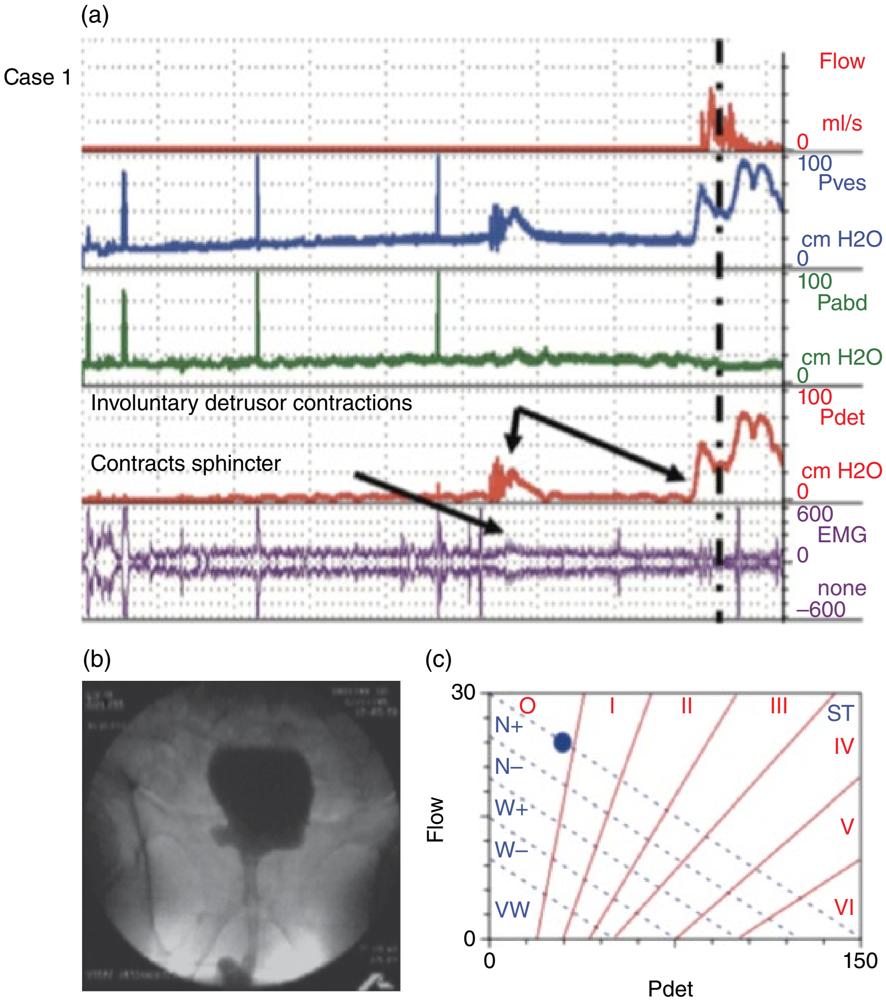

**Figure 140.6** Case 1. Urodynamic tracing of a man with two involuntary detrusor contractions; the terminal one causes incontinence. However, there is no bladder outlet obstruction. Maximum flow ($Q_{max}$) = 17 ml/s; detrusor pressure at maximum flow ($P_{det}$ at $Q_{max}$) = 22 cm$H_2O$. (b) Voiding cystourethrogram showing a wide open urethra during maximum flow. (c) Schafer nomogram plotting $Q_{max}$ versus $P_{det}$ at $Q_{max}$, yielding grade 0 voiding with excellent (N+) detrusor contractility.

## Cystoscopy

Urethrocystoscopy is recommended in evaluating men with suspected BPH with a history of microscopic or gross hematuria, prior lower urinary tract surgery, bladder cancer, and urethral stricture. It is not required and we do not recommend it in those patients who opt for medical therapy, unless there is another indication. AUA guidelines recommend use of cystoscopy in those patients where the “endoscopic appearance of the prostate may guide the choice of therapy in patients who have already decided to proceed with an invasive approach” [18]. This is particularly true in choosing newer minimally invasive therapies where the presence of a median lobe may be a contraindication.

## Detrusor underactivity (impaired detrusor contractility) and voiding dysfunction

The optimal management of patients with detrusor underactivity (DU) in the setting of voiding dysfunction deserves special consideration because, at the present time, there is no agreed method to determine whether or not the patient has BOO. Diagnosis and treatment are challenging for urologists.

DU is defined by the ICS as “decreased strength or duration of detrusor contraction that prevents timely and efficient bladder emptying” [37, 38]. The definition is highly subjective. Diagnostic tests used to help identify DU include mathematical calculations such as Watts factor,

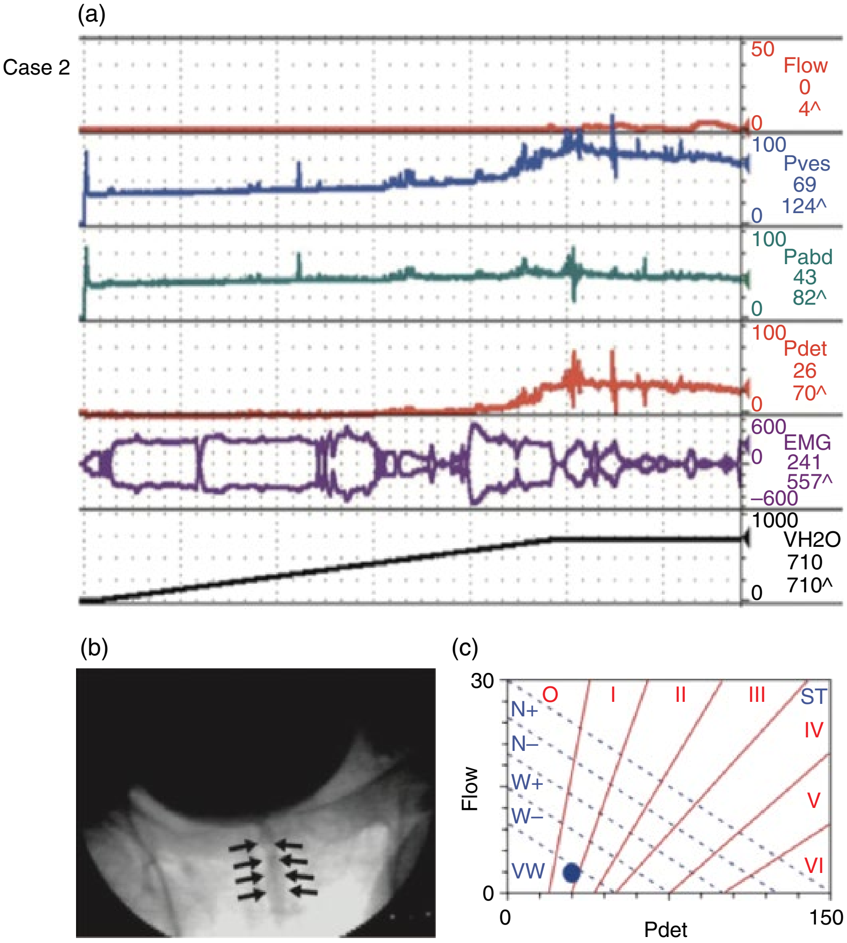

**Figure 140.7** Case 2. (a) Urodynamic study of impaired detrusor contractility (VW) in a 58-year-old man complaining of urinary frequency, urgency, occasional urge incontinence, hesitancy, and weak stream. First sensation of filling (FSF) = 272 ml; first desire = 491 ml; severe desire = 620 ml; bladder capacity = 710 ml; maximum flow ($Q_{max}$) = 6 ml/s; detrusor pressure at maximum flow ($P_{det}$ at $Q_{max}$) = 28 cm$H_2O$; maximum detrusor pressure ($P_{detmax}$) = 41 cm$H_2O$; bladder contractility index = 58; BOOI = 29. (b) X-ray obtained at $Q_{max}$ shows a narrowed prostatic urethra (arrows). (c) Nomogram reveals unobstructed voiding (grade 1) with very weak detrusor contractility. Bladder contractility index = 58.

indices such as BCI and bladder contraction coefficient, and urodynamic evaluation of $P_{det}Q_{max}$ and $Q_{max}$. None of these methods capture detrusor contraction duration (i.e. is the bladder contraction sustained sufficiently for complete bladder emptying?). Also, there is no objective definition of DU available [38]. DU describes defective detrusor function, while underactive bladder (UAB) refers to the symptoms resulting from decreased detrusor contractility. Such symptoms of UAB include sensation of incomplete emptying, double voiding, hesitancy, terminal dribbling, slow stream, prolonged voiding time, and intermittency [39–42]. DU is prevalent and identified in up to 48% of men and women during evaluation of LUTS [43, 44].

The main challenge in patients with detrusor underactivity and voiding symptoms is determining whether or not the patient has BOO. Standard pressure flow criterias for obstruction, such as the BOOI, require a $P_{det}Q_{max}$ >40 cm$H_2O$, but the vast majority of men with DU have $P_{det}Q_{max}$ <40 cm$H_2O$. When prostatic obstruction is encountered or suspected in the presence of DU, many surgeons hesitate to consider definitive surgical treatment of outlet obstruction because of fear that the procedure will be ineffective. Historically, studies had shown no benefit to outlet-reducing procedures in patients with both BOO and DU, but many recent studies have shown improvement in both subjective and objective outcomes. Improvements in IPSS and quality-of-life scores, reduction in postvoid residual volumes, increased $Q_{max}$, and elimination of need for clean intermittent catheterization (CIC) have all been reported [45–48]. Figure 140.9 shows a patient with severe LUTS and DU without diagnosable BOO who had successful outcome from transurethral resection of prostate (TURP). Those patients who have detrusor acontractility (DA) have a guarded prognosis with outlet surgery. Detrusor acontractility is the absence of any detrusor contraction during urodynamics. Such patients are unlikely to have return of volitional voiding after outlet surgery. Hence, UDS is invaluable in distinguishing between DU and DA, and identifying presence of BOO. We believe that most patients with combination of BOO and DU derive significant benefit from surgical treatment of their BOO.

**Figure 140.9** A 55-year-old man with severe lower urinary tract symptoms and detrusor underactivity without diagnosable bladder outlet obstruction who underwent transurethral resection of prostate with successful outcome. (a) Urodynamic tracing. At a bladder volume of 588 ml, he had a voluntary detrusor contraction. Maximum flow ($Q_{max}$) = 0.5 ml/s; $P_{det}$ at $Q_{max}$ = 28 cmH$_2$O; voided volume = 10 ml; BOO index = 27; bladder contractility index = 30; postvoid residual volume = 578 ml. (b) X-ray obtained at $Q_{max}$ shows no contrast in the prostatic urethra and a barely visible anterior urethra. (c) Pre and post transurethral resection of prostate uroflow tracings.

## Urinary incontinence

Urinary incontinence occurs in 5–10% of men with clinical BPH. Most of these patients have urgency incontinence. Sphincteric incontinence in men with BPH generally does not occur, unless the patient has a neurologic condition or has undergone prior surgery or radiation. By far the most common cause of sphincteric incontinence is radical prostatectomy for prostate cancer, followed by transurethral prostatectomy, particularly after radiotherapy for prostate cancer [49]. Less common causes are neurologic, including thoracolumbar neurologic lesions, such as spina bifida and multisystem atrophy (Shy–Drager syndrome), and iatrogenic, such as after abdomino-perineal resection of the rectum.

In the vast majority of patients after radical prostatectomy, incontinence is transitory and usually spontaneously subsides in a matter of months; however, it may take as long as 1 year for full recovery. Sphincteric incontinence that occurs in men who have undergone radiation (external beam or brachytherapy), on the other hand, often does not spontaneously remit. Rather, if incontinence improves, it is usually because of the development of a urethral stricture that begins a vicious cycle.

Treatment of the stricture usually results in recurrent incontinence, and treatment of the incontinence (sphincter prosthesis or male sling) is often complicated by the development of recurrent stricture [50, 51].

From a diagnostic standpoint, most patients who complain of a constant, dribbling, gravitational or stress-induced incontinence have sphincteric malfunction, and most who complain of urinary frequency, urgency, and urgency incontinence have an overactive bladder/detrusor overactivity. Despite this, there may be considerable overlap between these two conditions and both may coexist in the same patient. Sphincteric malfunction is the commonest cause of postprostatectomy incontinence (PPI), accounting for 95% of cases, but it may be accompanied by detrusor overactivity and/or low bladder compliance. As an isolated cause, detrusor overactivity causes about 5% of PPI [52–54].

On fluoroscopy, the classic appearance of postradical prostatectomy stress incontinence is the funnel of bladder–urethral anastomosis at rest, with contrast seen in the bulbar or distal urethra during increases in abdominal pressure (Figure 140.10). The presence of and size of the

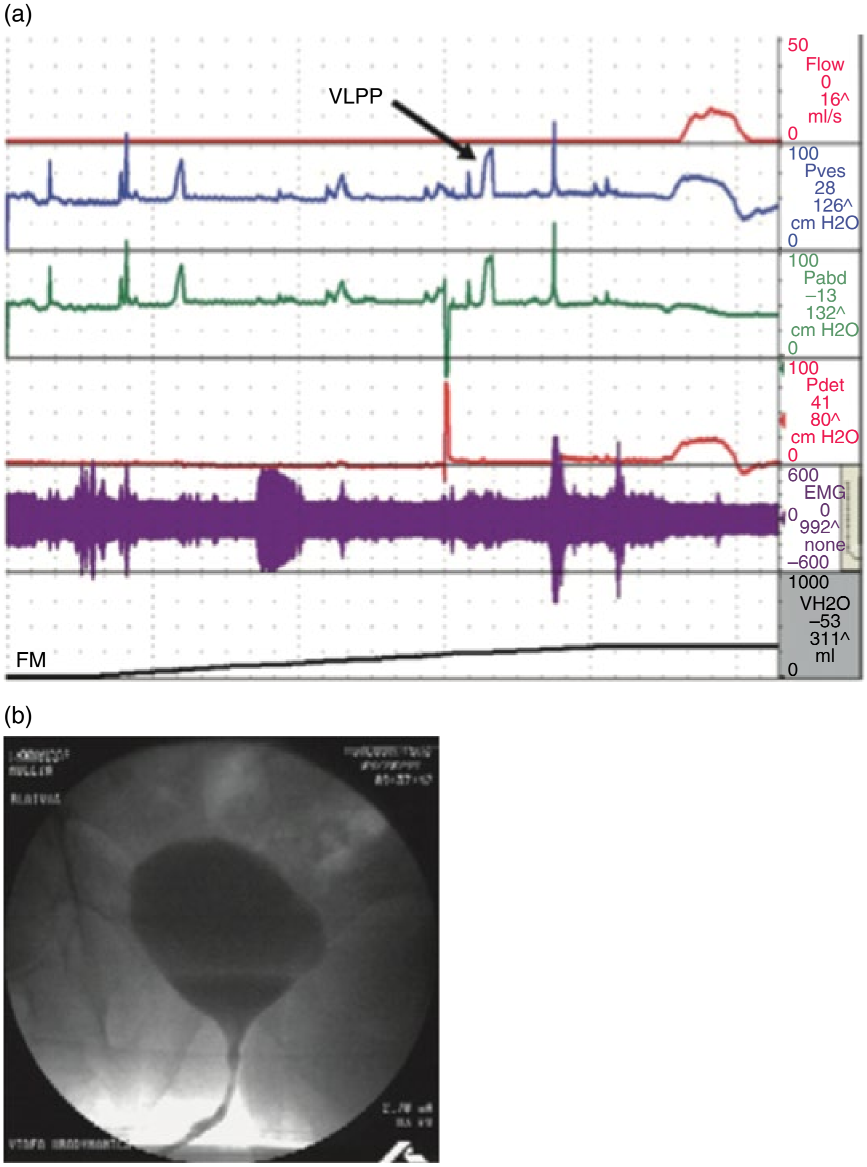

**Figure 140.10** (a) Urodynamic tracing of a 72-year-old man 7 years post radical prostatectomy. His only prior treatment for incontinence was a collagen injection. He wears absorbent pads daily and he changes them three times per day. First sensation of filling (FSF) = 211 ml; first urge = 299 ml; severe urge = 305 ml; bladder capacity = 311 ml; Valsalva leak point pressure (VLPP) = 84 cm$H_2O$; maximum flow ($Q_{max}$) = 16 ml/s; detrusor pressure at maximum flow ($P_{det}$ at $Q_{max}$) = 23 cm$H_2O$; maximum detrusor pressure ($P_{detmax}$) = 23 cm$H_2O$; voided volume = 317 ml; postvoid residual volume (PVR) = 0 ml. (b) X-ray obtained at VLPP shows contrast throughout the entire urethra.

urodynamic catheter used to measure leak point pressure may itself impact the recording and may mask sphincteric incontinence or suggest urethral obstruction when it is not clinically relevant.

In the majority of patients, the etiology of incontinence will be apparent after a careful history, physical examination, voiding diary, and pad test; however, detrusor overactivity and low bladder compliance can only be diagnosed with urodynamic studies.

## Conclusions

Indications for urodynamics in men with LUTS depend upon the threshold of the clinician for obtaining the most accurate diagnostic information. The underlying pathophysiology of LUTS in men with BPH consists of urethral obstruction, impaired detrusor contractility, detrusor overactivity, low bladder compliance, and increased bladder sensation. An accurate diagnosis of the underlying etiology can only be made with urodynamics, but most authorities agree that urodynamics is only necessary when surgical treatment is being considered. Pressure–flow evaluation has been and remains the only "absolute way of diagnosing BOO" [1]. Although PFS has not been shown to predict responses to medical therapy, numerous studies have demonstrated that those patients with proven obstruction benefit more from prostatectomy than those who are not obstructed [10, 26]. The efficacy of surgical treatment in patients with impaired detrusor contractility has not been resolved, but we believe that the majority of patients are, indeed, obstructed, and benefit significantly from outlet-reducing surgery. Regardless, from a clinical viewpoint, video-urodynamics serves no purpose unless the clinician bases therapy on the results of the study.

Notwithstanding these theoretical considerations, PFS is essential and video-urodynamics preferable for men who have failed conservative and surgical therapies, particularly in those considering more invasive treatment. Furthermore, video-urodynamics is recommended for men with known or suspected neurologic disease, including those with a history of spina bifida, diabetes mellitus, cerebral vascular accident, spinal cord injury, multiple sclerosis, Parkinson's disease, and multisystem atrophy. Men with a history of major pelvic surgery or prior pelvic radiation and LUTS should also undergo urodynamic evaluation.

Finally, even if video-urodynamics were found to have no clinical importance, it is still the best method of defining normal and abnormal physiology. Understanding physiology is the means by which new hypotheses are developed, leading to new research, new diagnostic methodologies, and, ultimately, newer and more effective therapies.

*Department of Urologic Surgery, Vanderbilt University Medical Center, Nashville, TN, USA*

## Introduction

Cystourethroscopic examination of the bladder and urethra remains the gold standard for the diagnosis of lower urinary tract disorders. It offers direct visualization of the bladder urothelium and provides initial access to the ureteral orifices for assessment and treatment of the upper urinary tracts. It is a cornerstone in the evaluation of gross and microscopic hematuria, and is useful in the investigation of lower urinary tract symptoms. Instruments passed through the cystoscope or specially designed resectoscopes allow minimally invasive diagnosis and treatment of identified pathology. This chapter summarizes the role of cystoscopy (both rigid and flexible) as well as recent innovations in office cystoscopy.

Cystourethroscopy is performed using either rigid or flexible endoscopes. Endoscopes are measured with the French scale and are available in sizes to accommodate both pediatric (8–12 Fr) and adult patients (16–25 Fr). The French scale is equal to the diameter of the cylinder in millimeters multiplied by 3, not the circumference as is sometimes thought. Increasing French units correspond to larger diameter endoscopes.

## Rigid cystoscopy

Rigid cystoscopes are multicomponent instruments that consist of a sheath, an obturator, a bridge, and a telescope (Figure 141.1). The sheath provides a connection to the irrigation system. An obturator is placed through the sheath that aids entry into the bladder through the urethra. Most are hinged to allow a better angled approach past the male bulbar and prostatic urethra. Once inside the bladder, the obturator can be exchanged for a telescope with a bridge that allows for the passage of a variety of treatment implements (i.e. wires, stents, ureteral catheters, laser fibers). The light source connects directly to the telescope, which uses fiber-optic illumination and a rod–lens imaging system to transmit the light and image to the eyepiece. Various lens angles enable the endoscopist to evaluate adequately the entire urethra and bladder. The 0° lens allows the best view of the urethra, providing a straight image. This degree lens is many times the most useful in patients with urethral stricture disease. A 30° lens is used to visualize the trigone, posterior wall of the bladder, as well as the lateral side walls. It is the most commonly used lens in rigid cystoscopy. A 70–90° lens is often used to assess the dome and anterior bladder neck.

Spring-loaded resectoscopes are typically used for the resection of bladder lesions and prostatic hyperplasia. These implements are best used in conjunction with a 30° lens–rod system and require the use of a large-bore sheath (24–26 Fr). Continuous-flow irrigation, which utilizes an outer sheath with both inflow and outflow ports, prevents the bladder from compressing on itself during the procedure. This allows the area of interest (e.g. a bladder tumor) to remain fixed in space to facilitate resection. Continuous irrigation provides for more efficient resection and enhanced visualization, especially in the setting of transurethral resection of the prostate (TURP).

Rigid cystoscopes provide a relatively large working port to accommodate a variety of accessory instruments. This is a major advantage; however, the large size of the rigid cystoscope decreases its applicability in males unless general or regional anesthesia is utilized. In addition, patients must be placed in the dorsal lithotomy position to facilitate an adequate examination. Rigid cystoscopy, therefore, is difficult to perform in the male patient outside of the modern operating room.

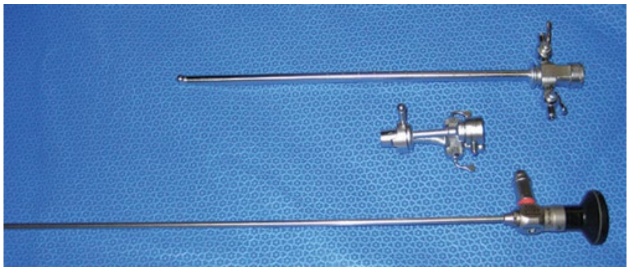

**Figure 141.1** Basics of the rigid cystoscope (from top to bottom): metal sheath with inflow and outflow ports, bridge, and rod–lens system to which the light source it attached.

### Procedures

Rigid cystoscopy is utilized to assess the bladder and upper urinary tracts for diagnostic evaluation of multiple clinical entities, such as hematuria, voiding complaints, and urothelial carcinoma. Retrograde imaging of the ureter and renal pelvis can be accomplished with the use of contrast injected through small catheters passed into the ureteral orifice under cystoscopic guidance. Ureteral stents are commonly inserted via the rigid cystoscope. Upper tract access for ureteroscopy may also be established with the use of wires and open-ended catheters. After wire passage has been confirmed with the use of fluoroscopy, the rigid cystoscope may be exchanged for a ureteroscope. Other uses are possible but have been largely supplanted with flexible cystoscopy.

### Technique

After obtaining informed consent and verifying proper instrument sterilization and availability, the patient should be prepped and draped in a standard sterile fashion. In both male and female patients, lubricant jelly should be instilled into the urethra before the procedure. If the meatus or urethra is unable to comfortably accommodate the cystoscope, dilation should be performed. This can be accomplished with the use of urethral sounds in a serial fashion. The urethra should be dilated to a diameter of at least 2 Fr units greater than the instrument (e.g. dilate to 26 Fr if utilizing a 24 Fr cystoscope).

In the male, the penis should be grasped and straightened as the endoscope is introduced to allow for inspection of the fossa navicularis and the anterior urethra. As the scope traverses the anterior urethra, the examiner's hand should be depressed to bring the penis parallel with the floor. This allows for examination of the membranous urethra and prepares the examiner to view the prostatic urethra. The verumontanum is noted when the examiner reaches the prostatic urethra. The prostatic lobes are seen laterally at this point in the examination. When the bladder neck is in view, it is often necessary for the examiner to depress the endoscope by dropping their hand toward the floor so as to account for the gentle upward angulation encountered before entering the bladder [1].

Once the endoscope is inside the bladder, a systematic evaluation of the entire bladder surface is performed in a routine and reproducible fashion. The trigone is the first landmark encountered when visualizing the bladder with a 30° lens. The examiner should follow the trigone laterally to identify the ureteral orifices effluxing clear urine. Next, attention should turn toward examination of the bladder floor beyond the trigone and the posterior wall. The lateral walls are then carefully inspected by rotating the lens side to side. The dome and anterior bladder wall are best viewed with the 70° lens. The scope should be rotated 180° to facilitate this part of the procedure, paying close attention to keeping the camera head level (if one is being utilized). The air bubble serves as the landmark for the dome. It is often necessary to apply pressure just superior to the pubic bone when visualizing the anterior bladder neck.

## Flexible cystoscopy

Flexible cystoscopy of the urinary tract is a fairly recent phenomenon. In 1973, Tsuchida and Sugawara reported utilizing a flexible "fibercystoscope" for examination of the bladder neck [2]. Since the development of the first purpose-built flexible cystoscope in 1984, flexible fiberoptic cystoscopy has become an accepted diagnostic and therapeutic modality, and today is the most commonly performed in-office procedure by the practicing urologist. The development of working ports, smaller cystoscope diameter with preserved image quality, active deflection, and most recently digital cystoscopes, have greatly enhanced the ability of the user to apply flexible cystoscopy for a variety of diagnostic and therapeutic applications. When compared to rigid cystoscopy, flexible cystoscopy is more comfortable for patients and can be performed with only local anesthesia. The deflection capabilities of the flexible cystoscope allow for easier passage through the bladder neck, as well as superior visualization of the anterior bladder wall (Figure 141.2).

However, there are disadvantages to flexible cystoscopy. Flexible endoscopes are costly and require more delicate care when compared to rigid cystoscopes. These instruments have smaller irrigating ports and lack a separate working sheath. As a result, changing lenses, assessing residual urine and repeat evacuation of irrigant and/or urine cannot be completed without entirely removing the endoscope or actually withdrawing gradually contents via the single, small-caliber channel of the irrigation port.

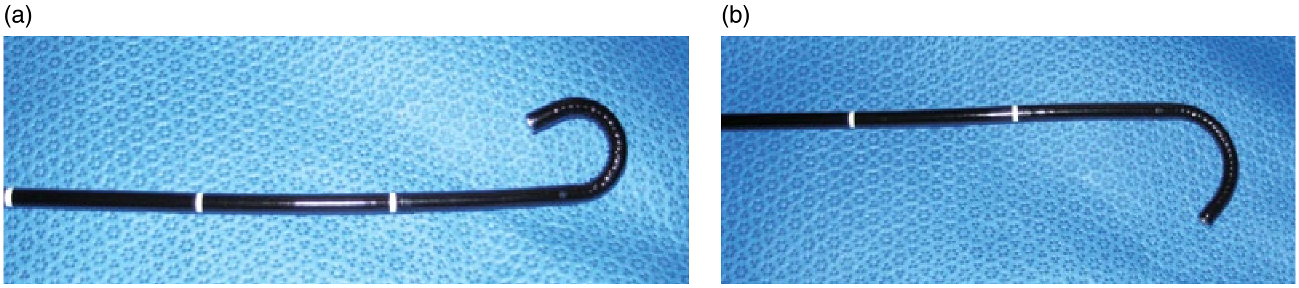

**Figure 141.2** (a, b) Tip of the flexible endoscope can be deflected 180–220° to allow visualization at nearly any angle.

Simply by its nature, the image obtained from a flexible fiber-optic cystoscope is inferior when compared to the rod–lens system employed in rigid cystoscopy. Fiber-optic technology has distinct imaging limitations owing to the finite diameter of the image-carrying glass fibers that make the pixelated "screen door" effect insurmountable [3]. There are generally three fiber-optic bundles within the shaft — two for light and one for the image. The image obtained by the fiber-optic bundle is a composite matrix of each individual fiber in that bundle, analogous to a newspaper photograph in which multiple dots merge into a single reconstructed image. Digital endoscopy, as discussed below, is able to overcome the limitations of fiber-optic endoscopy.

## Procedures

The single most common indication for flexible cystoscopy is evaluation for hematuria, whether gross or microscopic. Visualization of the entire urethra and bladder can be accomplished efficiently and without significant discomfort. Other diagnostic applications include its use in the evaluation of male or female voiding dysfunction. Flexible cystoscopy, however, is not indicated in the routine evaluation of male voiding dysfunction thought to be attributed to outlet obstruction from benign prostatic hyperplasia (BPH), as the endoscopic appearance of the prostatic urethra and bladder does not predict the response to BPH therapy [4]. However, endoscopic assessment is appropriate and often necessary in men being considered for surgical therapy of outlet obstruction to rule out the presence of urethral stricture or bladder neck contracture, especially in those individuals who have undergone prior transurethral surgery. It is essential as well to evaluate any suspected anatomic abnormalities.

In addition to diagnostics, there are many therapeutic office-based applications. These include the injection of urethral bulking agents for stress urinary incontinence and intravesical injection of botulinum toxin for voiding dysfunction. Removal of ureteral stents or of foreign bodies is another commonly employed procedure that is made safe, efficient, and reliable with the use of modern flexible cystoscopy. This can be done with grasping forceps, a retractable lasso device, or four-pronged grasping forceps with a retractable sheath. Once the cystoscope is introduced into the bladder and the object is identified, the grasping device is passed down the working channel and into the field of view. The object is then firmly grasped and the endoscope and graspers are removed as a unit under direct visualization.

Suspicious lesions in the bladder may be sampled in the office setting with the use of flexible biopsy forceps and electrocautery. When biopsies are to be obtained, a topical anesthetic agent (lidocaine 1% solution) is instilled into the bladder and left in place for 10 minutes prior to the procedure. An electrocautery unit and probe must be readily available in this situation. A nonconductive solution such as water or glycine must be the irrigant when electrocautery is used. Laser fulguration of small lesions is possible and is becoming increasingly used. This option is especially useful in patients with known rapidly recurring, low-grade, papillary tumors of the lower urinary tract.

## Technique

The patient should be prepared in a fashion analogous to that for rigid cystoscopy. In both male and female patients, lubricant–anesthetic gel should be instilled into the urethra before the procedure. A recent meta-analysis has demonstrated that subjects who received anesthetic-impregnated gel were 1.7 times more likely not to experience moderate-to-severe pain than subjects who had no intraurethral anesthetic instillation [5].

Examination of the urethra and bladder with the flexible cystoscope is performed in a slightly different manner from rigid cystoscopy. The anterior urethra can be viewed in a retrograde manner. The prostatic urethra should not be examined during retrograde passage of the endoscope as it will often appear obstructed. Instead, the prostatic urethra should be examined antegrade as the endoscope is being withdrawn from the bladder [6].

As with rigid cystoscopy, the bladder should be examined in a predetermined systematic fashion that the examiner can reliably duplicate to ensure adequate examination of its full contour. A standardized approach also aids in reliable documentation. The bladder should be cleared of turbid urine, clot, and debris prior to examination. The bladder is then filled with a sufficient volume to allow distention of mucosal folds. The bladder does not have to be distended as much as in rigid cystoscopy for adequate visibility. The first landmark in the bladder that is often seen is the air bubble at the dome. One systematic approach then is to evaluate the bladder by starting along the 12 o'clock position by pulling the endoscope toward the bladder neck and along the midline until the bladder neck is just entered. The endoscope is then returned to the dome and rotated from the 12 to the 4 o'clock position, and then from the 12 to the 8 o'clock position in a counterclockwise fashion. Next the scope is returned to a neutral position. The scope is then deflected to the six o'clock position to view the trigone. The 5, 6, and 7 o'clock positions are examined as previously described.

## Advances in office cystoscopy

The use of video cameras in endoscopy was introduced in 1956 by French researchers [3]. This development enhanced ergonomics, safety, and success rate for pathologic findings. This approach has many advantages, including the avoidance of contact with body fluids, patient education, and documentation through the use of digital camera technology [1].

Videoendoscopy with flexible scopes allows patients to visualize normal and abnormal anatomy, and thus helps them to understand their pathology. In male patients, videocystoscopy utilizing a monitor has been shown to produce a 40% decrease in the pain and discomfort level compared to those who did not view the procedure on the monitor [7].

Recently, the key advance in office cystoscopy has been the continued improvement and innovation in the visualization mechanism. Digital (distal sensor) endoscopy based on CCD (charge-coupled device) and CMOS (complementary metal oxide semi-conductor) chips has recently been introduced into the field of endourology. Digital sensors are composed of millions of photodiodes which convert photons into electric current that is later transformed into voltage, amplified, and converted to a digital form [3]. On both types of chips, the information is transferred to a controller box for image presentation or storage (i.e. the box that is connected to the cystoscope).

Distal sensor cystoscopes based on these technologies were introduced in an effort to provide urologists with better optical resolution, contrast, color differentiation, and improved durability. Digital image capturing allows for plug-and-play capability. Contemporary digital sensor endoscopes are able to meet the size requirements of flexible cystoscopy. They are already superior to flexible fiber-optic endoscopes in terms of weight and are thus easier to handle during procedures. Additionally, distal sensor cystoscopes do not require white balancing and camera focusing. *In vitro* evaluation has demonstrated that distal sensor cystoscopes are superior to fiber-optic cystoscopes in terms of resolution, contrast discrimination, and red color differentiation [8].

The first commercial digital flexible endoscope was the ACMI DCN-2010 introduced in 2005 (ACMI, Southborough, MA, USA). Quayle et al. compared this cystoscope with three contemporary fiber-optic scopes and found the digital scope to provide superior optics [9]. Okhunov et al. conducted a prospective clinical comparison of distal sensor (digital) and fiber-optic cystoscopes in over 1000 patients who underwent office-based cystoscopy. All surgeons found the digital sensor endoscopes to be lighter and easier to handle. Both subjective optical and functional metrics were significantly better with the distal sensor cystoscopes. Substantial differences were found with cystoscope deflection when instruments were placed in the working channel; however, the evaluating surgeons did not believe that this diminished function. Finally, both the fiber-optic and digital cystoscopes proved durable with a 0.2% repair rate during the study period [10]. It remains to be seen if distal sensor technology will ultimately prove cost-effective.

Narrow-band imaging (NBI) is a high-resolution endoscopic technique that improves detection of bladder tumors without the use of exogenous dye. The technology is available for both flexible and rigid cystoscopes. This enhanced visualization of mucosal and submucosal vasculature is made possible by the CCD chips. This narrow bandwidth of light (415 and 540 nm) is strongly absorbed by hemoglobin and penetrates only the surface of tissue. By narrowing the bandwidth of light from the flexible cystoscope, NBI improves the definition of the epithelial surface and emphasizes the mucosal microvessels. NBI has demonstrated superior sensitivity for identifying recurrent flat and papillary superficial bladder tumors in a surveillance setting when compared with standard white light cystoscopy. Early studies of this technology did not evaluate its benefit for the more difficult to detect lesions, such as carcinoma *in situ* [11]. More recent studies have demonstrated that NBI does improve carcinoma *in situ* (CIS) detection. Herr and Donat evaluated 427 patients for recurrent bladder tumors by white light cystoscopy followed by NBI cystoscopy during the same procedure. 103 patients (24%) had tumor recurrences of which 13% were detected only by NBI cystoscopy. NBI detected extrapapillary tumors or more extensive CIS in 58 patients [12].

Chen et al. compared white light imaging cystoscopy and NBI cystoscopy in the detection of urothelial carcinoma of the bladder in 143 patients [13]. NBI detected a total of 59 additional tumors (34 pTa, 17 pT1, 3 pT2, and 5 pTis) in 44 of 143 patients. The mean ± SD number of identified tumors per patient was 1.97 ± 0.67 for NBI and 1.78 ± 0.53 for while light imaging ($P = 0.01$). Tatsugami et al. evaluated the use of NBI cystoscopy for the detection of bladder cancer and analyzed its diagnostic efficacy in cases of CIS. A total of 313 biopsies were taken from 104 patients, including 161 from sites identified as potentially abnormal by NBI and/or white light imaging cystoscopy. In 26.9% of patients, bladder tumors were detected only by NBI [14]. The authors concluded that NBI was a simple and effective method for identifying bladder tumors because of its high sensitivity and high negative predictive value. Cauberg et al. also studied whether NBI improves detection of nonmuscle-invasive bladder cancer over white light imaging cystoscopy. This prospective trial was a within-patient comparison on 103 consecutive procedures on 95 patients. White light and NBI cystoscopy were performed by different surgeons who independently indicated all tumors and suspect areas on a bladder diagram. A total of 78 patients had a confirmed urothelial carcinoma; in 28 (35.9%) of these patients, a total of 39 additional tumors (26 pTa, 6 pT1, 1 pT2, 6 pTis) were detected by NBI, whereas 4 additional tumors (1.8%) (1 pTa, 1 pT1, 2 pTis) were detected by white light imaging. The detection rate of NBI was 94.7% versus 79.2% for white light imaging ($P < 0.001$) [15]. Shen et al. sought to evaluate if the improved detection of bladder tumors attributed to NBI could result from the second look inspection of the bladder. Investigators evaluated NBI and white light cystoscopy in 78 patients with suspected nonmuscle-invasive bladder cancer. The bladder was mapped with white light cystoscopy then NBI or vice versa within the same observation time. NBI identified significantly more additional tumors than white light imaging, with 36 (17.1%) tumors in 13 patients being detected by NBI only. The sensitivity of NBI versus white light imaging for detecting CIS was 87.8% versus 68.3% ($P < 0.05$) [16].

## Conclusions

As technology continues to evolve, office-based cystoscopic procedures continue to improve and expand. The ability to utilize flexible cystoscopy in an increasing number of clinical situations has benefitted both physicians and patients. At the same time, it continues to be the standard diagnostic evaluation tool for the practicing physician.

## Operating room setup and design

Before the patient enters the operating room (OR) all necessary equipment should be assembled and confirmed to be working properly. The OR setup should accommodate at least one table setup, the endoscopic video cart (Figure 142.1), the anesthesia equipment, the laser unit, the electrosurgical unit, the computer station, and the C-arm fluoroscopy.

Easy access to the electronic medical records (EMR) and hospital communication systems is necessary. Modern ORs are equipped with ceiling-mounted boom-arms for housing various surgical and anesthesiology equipment. Boom-arms provide an ergonomic advantage in arranging the OR, reducing the number of cables and trolleys occupying floor space, and making the positioning of cart-based equipment easier. Multiple arms are typically needed for housing all necessary equipment, with additional arms for surgical lights and video monitors. Video monitors mounted on boom-arms can be more easily positioned to accommodate the surgeon's and assistant's' preferences and to minimize neck strain. ORs equipped with boom-arm systems have decreased turnover, anesthesia and surgical preparation times, especially in laparoscopic surgery [1–3]. Before each case, staff should assess the current placement of the boom-arms and make any necessary changes prior to positioning both cart-borne equipment and the patient.

Dedicated space for C-arm X-ray is preferable, since the endoscopic OR is often used for various fluoroscopic procedures (e.g. ureteral stenting, ureteroscopy, percutaneous renal interventions). As many centers do not employ dedicated C-arms in their endoscopic ORs, the C-arm and radiology technician are often mobile, moving from room to room and employing cart-based monitors. This makes the relative placement of necessary equipment crucial as the C-arm and monitors may need to be positioned after the patient is in the room or removed from the room prior to the conclusion of the case. This poses a special challenge in small ORs. Ideally, there will be adequate room to move about freely, to assist the anesthesiologist, and to perform documentation (Figure 142.2).

We recommend a 7 × 7 m (23 × 23 ft) room for endourological ORs. A 3.5 m (12 ft) high false ceiling with a 60 cm (2 ft) gap is used to accommodate cables, wires, piping and air conditioning vents. A powerful active suction device should be available for suction of fluids directly from the patient drapes (Neptune Waste management system, Stryker®, Kalamazoo, MI, USA). If such a system is unavailable, the floor of the endourological OR must be sloped towards a centrally placed drain to allow efficient, hygienic drainage of fluids [4].

If a dedicated cystoscopy suite is used for lower tract endoscopy, a sterile supply area should be dedicated nearby for equipment storage and commonly used supplies may be stored in the OR itself. If a dedicated suite is not employed, the sterile supply store should be organized such that necessary kits and supplies are stored nearest to the rooms used for cystoscopy.

### Lighting

It is important to have adequate lighting during endoscopic procedures. Often, lighting must be changed during the case to accommodate easy visualization of video monitors. We recommend a minimum of 1500 lux for the sterile field and 500 lux for the remainder of the room. We recommend using twin-dome lights that provide a shadowless white light as high as $3 \times 10^5$ lux 1 m

from the field. In the past, OR lights employed halogen bulbs. At present, LED bulbs are favored as they provide high-quality cold white light and are considerably more durable than halogen bulbs. Control of the light placement and levels should be available to the surgeon in sterile field as well as on a conveniently placed OR control panel to allow easy manipulation by all team members.

## Table

The operating table for endoscopic procedures should be able to support the patient in lithotomy and supine positions without injury or instability. We recommend the use of a specialized cystoscopy table if a dedicated cystoscopy suite is available. These tables lack some of the functionality of the operating tables described below but are adequate for lower tract endoscopy performed in low lithotomy position. Typically, cystoscopy tables are wide to allow comfortable patient positioning without armboards and have lightweight, easily detachable leg sections to allow for easy removal once the patient's legs are placed in the stirrups. These tables also have eccentrically placed bases to allow for free movement of the C-arm.

Many centers perform lower tract endoscopy in general ORs. Tables in these rooms should be constructed using rust-proof stainless steel. Construction materials should be radiolucent and the table base should be eccentrically placed to allow for C-arm use. With modern tables the table top can be moved relative to the base to allow for proper C-arm positioning. Occasionally, patients must be placed backwards on the table, with their legs over the head section to allow for lithotomy

positioning and C-arm use. The table should be easily movable on built-in wheels with central locking. The head and leg sections should be separable with a gynecological cut-out at the end of the body section. Attachment points for stirrups and fluid collection devices are necessary to allow for an anatomically correct lithotomy position. The table should also be capable of moving relative to the locked base, increasing or decreasing table height, and tilting to allow Trendelenburg, reverse Trendelenburg, and laterally rotated positioning. Ideally, bed positioning should be controlled via remote control available within the sterile field. However, management of bed position often falls to the anesthesia team, as control of the patient's airway can be compromised by repositioning.

### Obesity

Given the rise in morbid obesity, the weight of the patient should be considered in selecting the OR table, lithotomy stirrups, and any other weight-bearing equipment. With the increased utilization of weight loss surgery, robust operating tables have been developed to ensure patient safety and may be considered if a patient is especially obese. Adequate equipment for patient transfer should also be available as traditional roller-boards or drag sheets may be inadequately sized.

## Documentation and operating room integration

Archival of patient-related data for later reference and follow-up is important for clinical management, teaching, research, and satisfying medicolegal requirements. Such archiving is performed via paper documents, electronically, or both. Electronic record-keeping is virtually ubiquitous and modern EMR provide convenient access to the whole medical record, including imaging, financial records, and administrative information. The EMR software should adhere to the Health Level Seven standards to allow for seamless handoff between different software applications. In medical imaging, electronic picture archiving and communication systems (PACS) have been developed in an attempt to provide economic storage, rapid retrieval of images, access to images acquired with multiple modalities, and simultaneous access at multiple sites. The universal format for PACS image storage and transfer is DICOM (Digital Imaging and Communications in Medicine). Non-image data, such as scanned documents, may be incorporated using consumer industry-standard formats such as PDF (portable document format), once encapsulated in DICOM. A PACS consists of four major components: the imaging modalities such as CT and MRI, a secured network for the transmission of patient information, workstations for interpreting and reviewing images, and archives for the storage and retrieval of images and reports.

In the modern OR, integration of audio-visual (AV) signals and control of the data streams from endoscopic instruments, cameras, and fluoroscopy is vital. Through a central control, it should be possible to route any AV signal to any monitor in the OR. Ideally this control system would be available in the sterile field, but quite often it is located at the nursing computer station. The ability to record or transmit this information to separate locations is especially useful for education, and most surgical meetings devote major sessions to live operative workshops. Installation of such systems presents a large upfront expense, but is much cheaper than erecting temporary facilities for similar purposes and should be seriously considered during planned renovations.

## Universal protocol

The Universal Protocol (UP) for preventing wrong site, wrong procedure surgery was developed by the Joint Commission on Accreditation of Healthcare Organizations (JCAHO), and has been in effect since July 1, 2004 for all accredited hospitals, ambulatory care, and office-based surgery facilities (goo.gl/wJZWbO). The UP consists of three distinct parts: preprocedure verification, site marking, and a time-out performed immediately prior to the procedure. The UP is applicable to any setting where invasive procedures are performed, not just the OR setting. The Joint Commission International is a branch of the JCAHO that sets and enforces accreditation standards, including the UP, in more than 81 countries.

In accordance with the above regulation, before starting any intervention on the patient, all personnel in the OR follow "time-out" to identify (a) correct patient, procedure, site, side, position, equipment, implants, images, medicines (labeled); (b) allergies, antibiotics; (c) whether all labels from previous case are out of room. It is crucial that all OR staff are present and attentive during the time-out, and that any concerns are raised before the procedure is started.

## Room preparation

Operating room setup for transurethral, vaginal, and lower tract prosthetic surgery is discussed here. Transurethral procedures include cystoscopy, transurethral resection of bladder tumor, transurethral resection of the prostate, and direct visual internal urethrotomy. Increasingly, lasers are being employed in place of diathermy, which requires OR staff to familiarize themselves with the unique safety concerns that accompany high-energy light sources. Endourologic instrumentation and equipment will vary depending on the operative procedure. Vaginal procedures include urethral slings, anterior, posterior and apical repairs of pelvic organ prolapse. These surgeries may use native grafts or synthetic mesh for the repair.

With the current advancements in the understanding of pathophysiology of urinary incontinence and pelvic organ prolapse, most of these can be managed through a vaginal approach with or without usage of graft material. Similarly, prostheses are increasingly being placed for urinary incontinence (artificial urinary sphincter) and for erectile dysfunction (inflatable or malleable penile prosthesis). The OR should be equipped to handle all these procedures.

In general, two nurses are required for setup. The scrub nurse is responsible for setting up the instrument table, ensuring that the instruments are properly sterilized, functioning properly, and neatly arranged for easy availability. Each medical center should develop checklists for each procedure to prevent delays caused by missing equipment. Nurses and surgeons should collaborate to ensure checklists are complete without being excessive, and should specify which instruments will *always* be used and which instruments *may* be used. The former should be opened and arranged prior to the start of the case, while the latter should be retrieved from central supply but kept unopened until they are needed.

## Patient preparation

While the scrub nurse is preparing the sterile setup, the circulating nurse reviews the patient's chart. The circulator acts as the patient's advocate, reviewing the OR sequence with the patient, identifying the correct operative site and laterality, addressing any concerns the patient may have, and communicating with the patient's family. Indications for antibiotics and prophylaxis against deep vein thrombosis are reviewed and the necessary medications and equipment are retrieved if necessary. The patient's anticoagulation status should be reviewed. If withholding anticoagulation is indicated the circulator should confirm that the patient has not taken this medication. The availability of blood products for possible transfusion should be checked before the circulating nurse brings the patient into the OR.

After anesthesia is induced, the patient is positioned appropriately based on the procedure. Lower tract endoscopy, vaginal surgery, and placement of artificial urinary sphincters is performed in the lithotomy position, whereas penile prostheses can be placed while supine.

For lithotomy, patients must be positioned such that when the leg portion of the table is removed, the buttocks are at the table's edge, over the gynecologic cut-out. After placing antiembolic compression stockings or sequential compression devices, *two* team members should raise the patient's legs slowly and simultaneously. Care must be taken to support the knees as the feet are positioned in gel-padded footrest stirrups (Figure 142.3). Padded patient supports and foam sheeting should be used to prevent pressure on the nerves and soft tissues of the upper and lower extremity. Improper positioning can result in nerve damage, venous thrombosis, compartment syndrome, and hip-joint dislocation. Both arms should be secured on padded armboards to prevent injury to the patient's fingers or hands when the table is raised or lowered. There are a number of positioning techniques to prevent injury (Table 142.1).

If monopolar diathermy is being used, a dispersive electrode is fixed distant to bony prominence. No such lead is necessary with bipolar instruments. Any visible contamination of the surgical site should be removed and clipping of hair may be performed. There is level I evidence that there is no difference in surgical site infections between shaved and unshaven incision sites [5]. However, if hair is to be removed, electric clippers are associated with lower infection rates than shaving with a razor. A recent Cochrane review found no difference between day-before and day-of-procedure hair removal but current Association of periOperative Registered Nurses (AORN) guidelines recommend hair clipping the day of the surgery and only if necessary for the procedure [5]. Next, skin preparation is done using an antiseptic solution. A large randomized controlled trial (RTC) of clean-contaminated surgeries and a smaller RTC examining urologic procedures shows lower rates of surgical site infections with chlorhexidine gluconate and isopropyl alcohol as compared to povidine iodine when used for at least 5 minutes [6–8]. We typically use the former (Chloraprep®, CareFusion, El Paso, TX, USA). Because of apprehension of infection associated with prosthetics, surgical site preparation varies significantly between surgeons. While a 10-minute manual scrub of the surgical site is common practice, there is no evidence supporting any specific time requirement to reduce infection rates for penile implant procedures [8]. There is no urology-specific study examining surgeon hand-cleansing method and infection rates, but a large multidisciplinary prospective RTC showed no difference between traditional hand-scrubbing and alcohol-based solutions.

Once the surgical site is properly cleaned, surgical drapes should be appropriately placed to minimize the risk of the prosthesis contacting the patient's skin. Adoption of a no-touch insertion technique has been

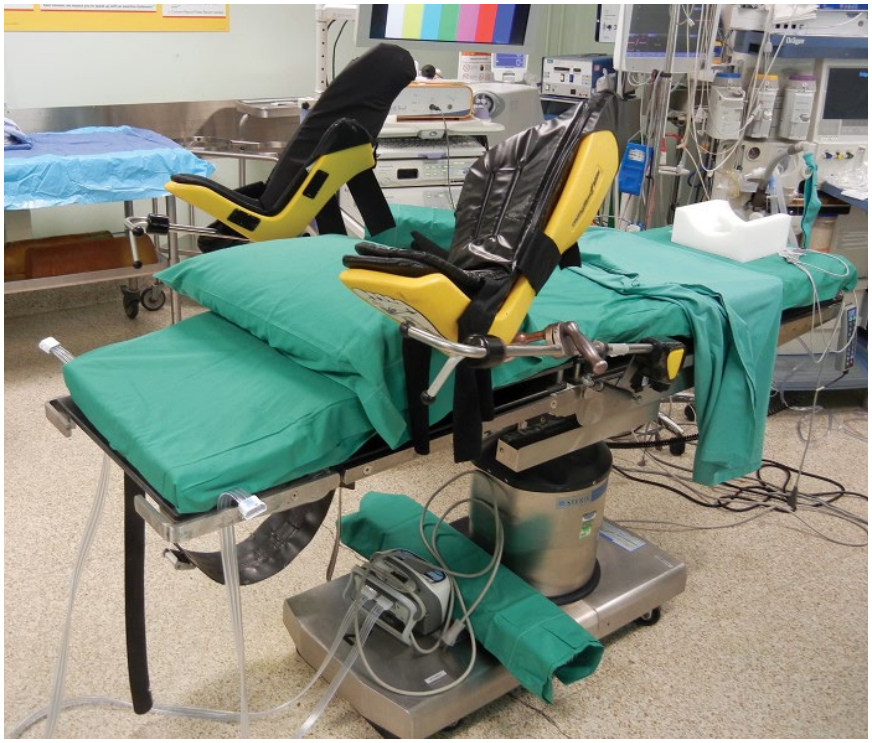

**Figure 142.3** Operating table with Yellofins® stirrups.

**Table 142.1** Complications related to poor patient positioning.

| Complication | Consequence | Positioning technique |
|---|---|---|
| Common peroneal nerve injury | Inability to dorsiflex the foot. "Foot drop" | Ensure the lower leg does not rest dependently on the stirrup. Avoid excessive hip flexion and knee extension |
| Femoral nerve injury | Inability to flex the hip or extend the knee | Avoid hip flexion >90°, minimize internal and external hip rotation |
| Obturator nerve injury | Inability to adduct the leg, hip instability | Avoid leg abduction greater than 30–45°, combine abduction with hip flexion |
| Brachial plexus injury | Varies, weakness and loss of sensation in the upper extremity | Shoulder abduction should be less than 90° or shoulder braces should be used |
| Ulnar nerve injury | Numbness, of the ring and little finger, weak grip | The arm should be pronated and properly padded |
| Compartment syndrome | Ischemia and necrosis of the leg, potential need for fasciotomy | Traction pads to prevent slipping when in Trendelenburg, minimize procedure time and time in Trendelenburg |

shown to significantly decrease infection rates [7]. Ioban™ or similar adhesive barriers can be used to secure the drapes and minimize the amount of exposed skin [9].

## Equipment preparation

### Transurethral surgery

Transurethral surgery is performed through a rigid cystoscope. The outermost piece of the cystoscope is the sheath, and all lenses, resection tools, and fluids must pass through it. The lens is connected to the sheath by the bridge, which has one or two channels through which wires and laser fibers can be passed. The bridge is typically labeled with its outside diameter and the diameter of its working channels(s). Typical cystoscope and resectoscope kits include 0, 30, and 70 lenses, outer and inner sheaths in 19 Fr or 21 Fr, Timberlake, blind and visual obturators, a trumpet valve working element, one and two channel bridges, detachable stopcock for irrigation tubing, flexible grasping forceps, and rigid biopsy forceps. Other kits with 12 (Olympus) and 120 (Olympus and Storz) lenses as well as 15 and 17 Fr sheaths are available on request. If a patient

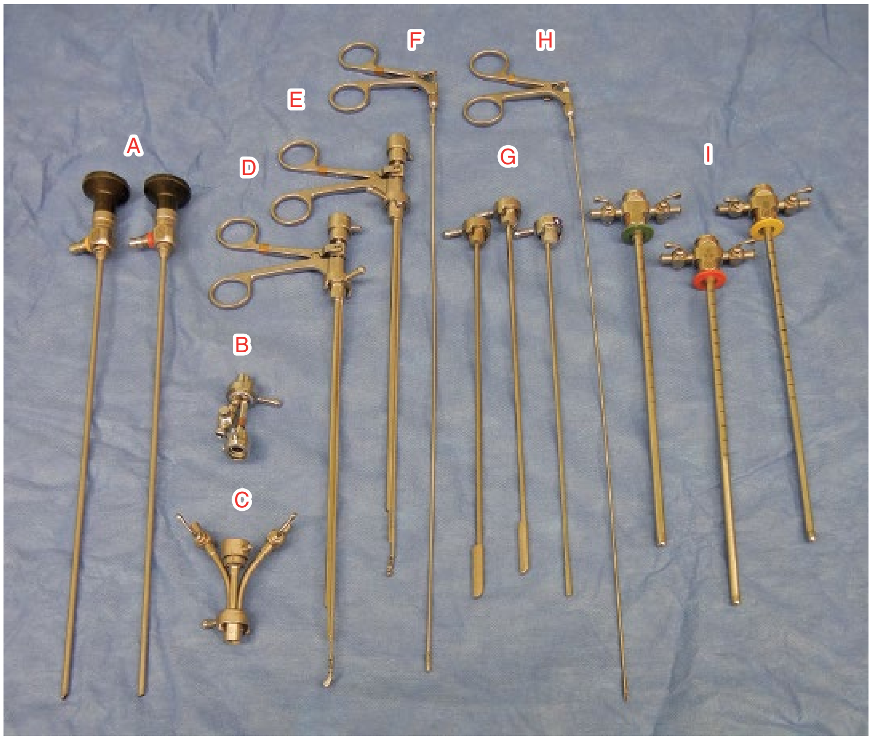

**Figure 142.4** Cystoscopy set. A, Telescopes; B, single channel bridge; C, -channel bridge; D, rigid biopsy forceps; E, rigid foreign body forceps; F, flexible foreign body forceps; G, visual obturator; H, flexible biopsy forceps; I, sheath.

has a high bladder neck, a large prostatic median lobe, or other difficulty anatomy, the use of an Albarran bridge may help to direct any wires, fibers, or catheters that would otherwise be difficult to place.

Cystoscopes are assembled in a stepwise fashion with each subsequent piece fitting over and attaching to its predecessor. A typical initial setup is obturator (visual or nonvisual obturator), bridge, sheath. Visual obturators allow a telescope to be placed inside so the urethra can be traversed under direct visualization. The light source attaches to the lens, while the irrigant tubing attaches to the sheath. Once the cystoscope is in the bladder, the obturator is removed and replaced with the resectoscope (Figure 142.4).

From inside to outside, a resectoscope consists of a lens, working element with loop, outer sheath, and inner sheath. The working element typically has a trumpet valve style articulator. Fluid inflow and outflow are attached to the sheaths. Resectoscopes produced by Storz have fluid inflow through the inner sheath and outflow through the outer sheath, while Olympus resectoscopes have both on the outer sheath. This allows inflow and outflow to function with only the outer sheath inserted, leaving a larger working channel. A special attachment is available for the Storz that allows inflow and outflow through the outer sheath.

UroLift® is a novel device that places implants made of nitinol, stainless steel, and PET suture to lift and compress the lateral lobes of the prostate to treat benign prostatic hyperplasia (BPH)-related urinary symptoms. The UroLift kit includes its own specialized cystoscope, designed for application of the implants. Each implant device is placed by a single-use UroLift delivery device under direct visualization. Because these devices are not reusable, several devices should be available but unopened before the procedure begins. Typically 4–6 implants are needed.

After patient positioning, the leg portion of the surgical table should be removed and the appropriate fluid collection device should be placed and connected to suction. Various proprietary drapes are available with inbuilt collection system (Kimberly-Clarke®, Reigate, Surrey, UK; Microtek Medical, Columbus, MS, USA; G Surgiwear, Shahjahanpur, UP, India).

A typical setup for transurethral resection procedures is described below:

### Back table

Cystoscopy pack with back table drape, patient drapes, irrigation "Y" tubing, transurethral resection (TUR) set, k-y jelly, a marking pen, and labels for labeling fluids, a 10 and 20 ml syringe, a Telfa pad (Kendall, Covidien, Mansfield, MA, USA) for specimens, a disposable graduated cylinder and two small basins and three disposable towels. Gowns and gloves should also be opened and available. These should be arranged with attention to when each piece of equipment will be needed.

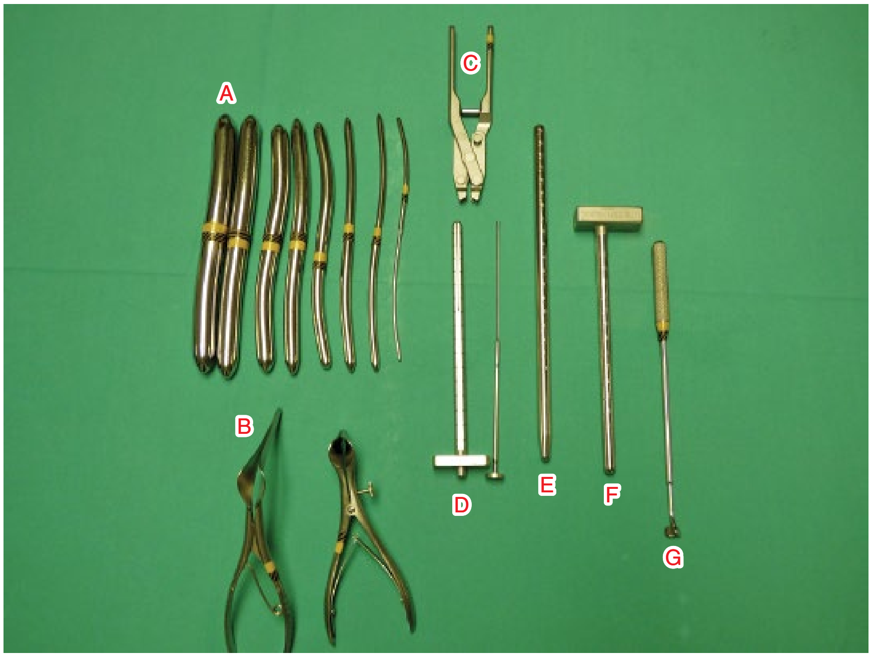

**Figure 142.5** A, Hegar dilators; B, nasal speculum; C, crimper; D, Furlow introducer; E, measuring rod; F, dialmezinsert device; G, insertion tool.

Patient drapes are placed in the left lower corner of the back table. All cords to be passed off are placed in the left upper corner of the back table (camera, light cord, cysto "Y" tubing, bovie or bipolar cord). A towel with k-y jelly is placed beside the drapes. The Van Buren sounds should be placed in sequential order from smallest to largest. The double channel bridge should be attached to the 30° telescope and the 70° bridge should be attached to the single channel bridge. A nipple should be placed on each channel and all stopcocks placed in the OFF position to control the fluid channel. These should be arranged between the 22 ft cystoscope sheath with obturator and the resectoscope (Figure 142.5).

### Prep table

For female patients, a prep set is opened that contains basins to hold the appropriate antiseptic solution according to surgeon preference and patient allergies. Of the 10 sponges in the preparation pack, 5 should be used for patient preparation. The additional 5 sponges in the tray should be placed on the back table. For male patients a 26 ml Chloraprep applicator stick is used.

### Resection kits

Monopolar, bipolar and laser resection kits have different components.

- *Monopolar*: Continuous flow resectoscope set 26 Fr/28 Fr; outer sheath, inner sheath, visual obturator with single channel, Timberlake deflecting tip obturator, passive or active type working element for the resectoscope, a disposable loop, and a Toomey syringe or Ellik's evacuator. Adequate 1.5% glycine and 0.9% normal saline should be available for intraoperative and postoperative irrigation respectively.
- *Bipolar*: Gyrus-ACMI (now an Olympus company), Olympus and Karl Storz manufacture bipolar resection systems. Of these the Gyrus PK® Superpulse® is the most extensively studied and widely used. Each set is specific to the manufacturer and typically includes a 25.6 Fr /27.6 Fr inner and outer sheath, visual sheath, Timberlake obturator, Iglesias working element and disposable loop. The irrigant of choice for this procedure is 0.9% normal saline.
- *Laser*: Holmium:YAG and KTP and thulium are commonly used lasers for prostatic diseases. The resectoscopes/cystoscopes for these are separate from the above as well as from each other. Each basic set has similar components (i.e. outer sheath, inner sheath, obturator, working element), but the working elements have specially designed channels to accommodate the laser fiber.

## Prosthetic surgery

The use of prosthetics in urology has become commonplace in recent years. Advancements in device design and infection prevention strategies have encouraged patients and surgeons alike in choosing inflatable penile prostheses and artificial urinary sphincters.

Before the procedure it is vital that the circulator nurse confirm the patient has received the necessary antibiotics and that the antibiotics for irrigation are in the room. The scrub nurse should confirm the availability of all the

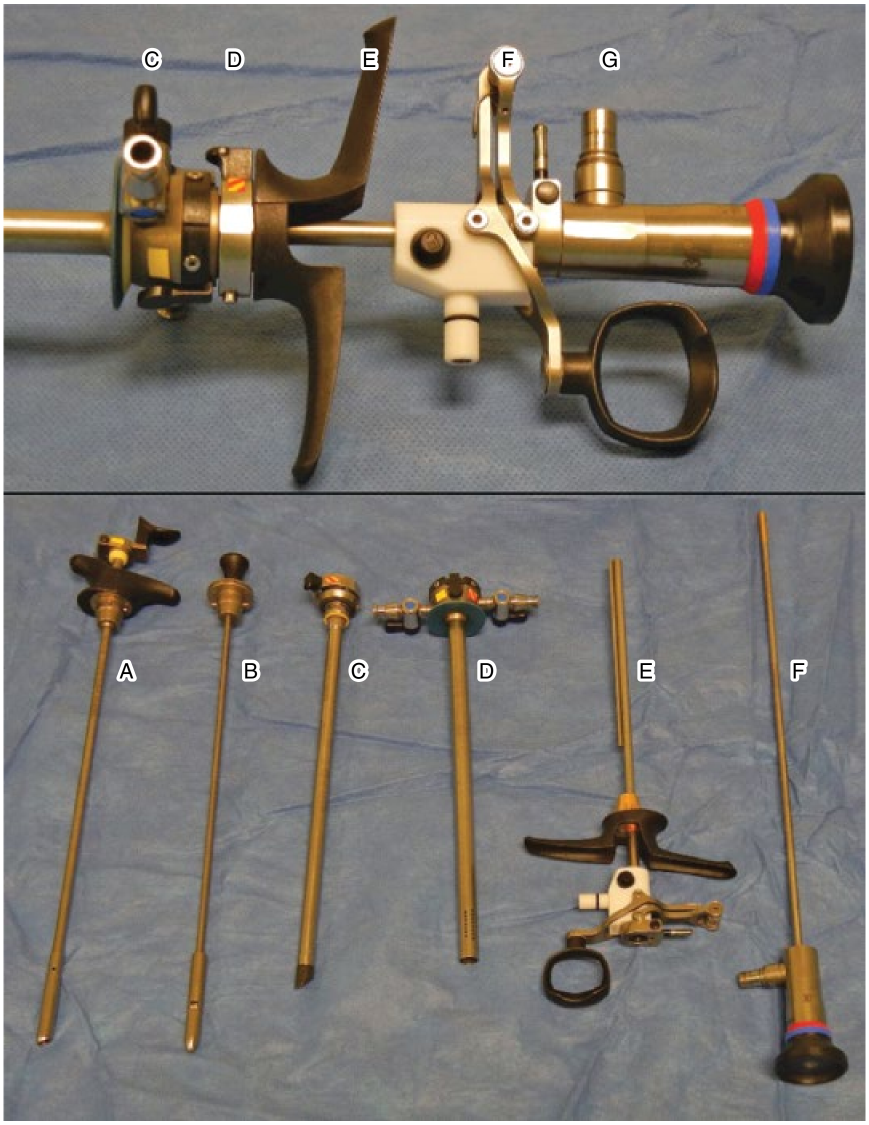

**Figure 142.6** Resectoscope, left: disassembled right: assembled. A, Visual obturator; B, Timberlake (blind) obturator; C, inner sheath; D, outer sheath; E, working element with trumpet valve control; F, telescope; G, light source connector.

various sizes of the prosthetic and the special instruments needed to place it (Figure 142.6).

A typical setup for insertion of a penile prosthesis is described below.

### Back table

Major prep pack: table cover, 5 half sheets, 2 wetproof drapes, 12 towels, 1 mayo cover, 2 wet proof towels, 4 gowns. Urology minor set, penile prosthesis set, Lone-Star retractor with hooks, dilamezinsert inserter, no. 15 blade with handle, needle protector, marking pen, monopolar pencil, bipolar forceps, suction tubing and tip, 10 ml syringe for the Foley catheter, 20 ml syringe ×2 for flushing the prosthesis tubing, 60 ml syringe ×2 for filling the prosthetic and reservoir, 14 Fr Foley catheter and drainage bag, steridrape, marking pen, labels for medication and fluids, small basins for antibiotic irrigation, tray for prosthesis soaking. Rifampin–gentamicin solution should be available for irrigation and/or device soaking if indicated. At present, the Boston Scientific inflatable prosthesis devices are impregnated with antibiotics and no additional preparation of the device is necessary.

### Mayo stands

One mayo stand should be draped in the typical fashion with an impervious steridrape placed over it. A small round basin, large round basin, rectangular tray, and all syringes are placed on this stand. Rubber-shodded mosquito clamps are kept in the small basin. The large basin and the rectangular tray are filled with 0.9% saline. Hegar dilators, nasal speculum, measuring devices, dilamezinsert, the Furlow tool, and the quick-connect devices should be placed in the rectangular basin. Any instrument placed here should be rinsed in sterile water beforehand.

The second mayo stand should be draped in the normal fashion and have Adson forceps, short Debakey forceps, suture scissors, 4 straight hemostasis, 4 curved hemostats, 1 Allis clamp, and 1 Lahey dissector arranged neatly on it.

#### Double ring stands

Both stands should be draped and large basins appropriately placed. One should be placed on each side of the patient and filled with 0.9% saline for glove washing before the prosthesis is handled.

Setup for placement of an artificial urinary sphincter and placement of a penile prosthesis are very similar. Additional equipment includes a ¼ inch Penrose drain or vessel loop to place around the urethra, Kittners and methylene blue. Hegar dilators, nasal speculum, measuring device, dilamezinsert, Furlow tool, and quick-connect devices may be used.

### Vaginal surgery

Room setup for vaginal surgery is similar to endoscopic surgery, with a specific vaginal surgery kit available at most centers.

#### Prep table

For female patients a prep set is opened that contains basins to hold the appropriate antiseptic solution according to surgeon preference and patient allergies. Of the 10 sponges in the preparation pack, 5 should be used for patient preparation. The additional 5 sponges in the tray should be placed on the back table. Instruments that may be useful in vaginal surgery include weighted vaginal retractor, Lone-Star retractor, Breisky-Navratil vaginal retractor, Sim's speculum, Stamey needles, Heaney curve-tip needle holders, and Mueller S-shaped dissecting scissors.

## Energy sources

### Diathermy

#### Monopolar

Monopolar instruments are the most readily available and commonly used method for electrosurgery. All electrosurgery instruments have two poles (bipolar) and electrical current runs between two poles. Monopolar diathermy employs an active electrode located in the cutting instrument, and a dispersive electrode located in a metal or metalized plastic pad attached to the patient's skin. Because the cutting instrument is small, the concentration of current is highest where it contacts the tissue. In contrast, the dispersive electrode is large, allowing current to flow without damage the tissue. Ideally, the dispersive electrode should be between the site of surgery and any metal implants the patient may have. This avoids current running selectively through the implant and causing tissue damage. If the patient has metal implants on both sides of the body (i.e. bilateral hip replacements) the pad should be placed between the implants where possible.

Monopolar instruments can cause severe burns if contact with the dispersive electrode is insufficient or if there is tissue in contact with other metal objects that can "leak" current. In addition, if current from a monopolar instrument demodulates, as can happen when the current arcs through the air to the tissue, the frequency of the current can drop into the range commonly used by implantable pacemakers and defibrillators. This can lead to malfunction as the device interprets the current as cardiac in origin and can respond inappropriately [10].

It is important to note that a monopolar generator can be used in any setting that requires monopolar diathermy and a single cord can be used with multiple instruments. Monopolar generators and instruments are less expensive and more readily available than bipolar instruments.

In endourology, monopolar instruments *require* the use of nonconductive fluids such as sorbitol, glucose, or glycine to prevent dispersion of current through the irrigant. Because these solutions are hypotonic, prolonged exposure through procedures such as transurethral resection of the prostate (TURP), can cause TUR syndrome. TUR syndrome is characterized by dilutional hypervolemic hyponatremia, which can lead to congestive heart failure, pulmonary edema, seizures, coma, and death. Because of this, procedure time should be limited to 90 minutes when monopolar resection is used.

#### Bipolar

Bipolar instruments function using the same principles as monopolar instruments, with a current running between two poles. Unlike monopolar instruments, which require a large dispersive electrode elsewhere on the body, bipolar instruments have both electrodes located within the instrument. Monopolar instruments send current through the patient's whole body as it flows between the active and dispersive electrode. Bipolar instruments only send current through the target tissue located between the electrodes. Monopolar and bipolar endoscopic instruments come in various configurations (Figure 142.7).

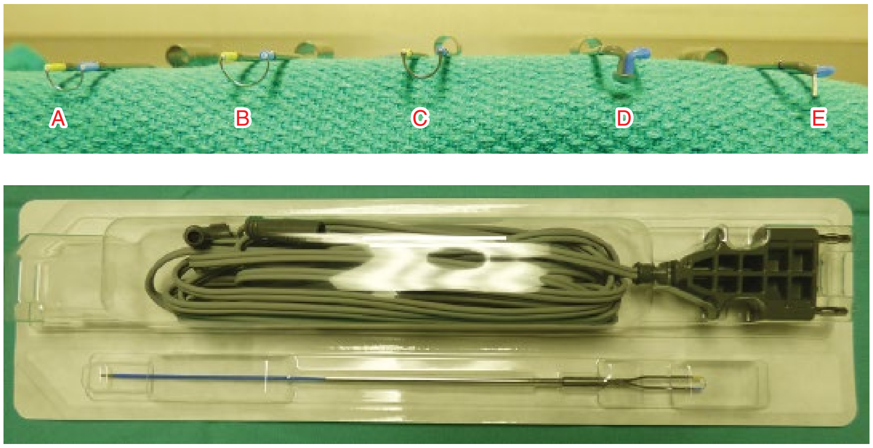

**Figure 142.7** Bipolar implements. Top: A, small loop; B, large loop; C, band electrode; D, button electrode; E, needle electrode. Bottom: Implement in packaging with dedicated cord.

Because current runs so directly between the on-instrument electrodes, bipolar instruments can be used with saline irrigant, allowing longer procedure times without concern for TUR syndrome as described above. This allows for extensive resection of large prostate glands that would have required a staged procedure with monopolar instruments. Resection time, intraoperative blood loss, need for transfusion, hospital stay, and catheterization times are all decreased in bipolar TURP as compared to monopolar TURP, while short- and medium-term outcomes are the same [11–14]. We suggest the use of bipolar resection of the prostate over monopolar resection when possible.

Although bipolar instruments decrease procedure-associated morbidity, they do pose a significant increase in cost. Bipolar generators are more expensive and less common than monopolar generators and cannot be used interchangeably the way monopolar generators can. In addition, if multiple instruments are to be used, monopolar instruments can be attached to the same power cord, while bipolar instruments each require their own.

### Laser

Since their introduction in urologic procedures in the late 1980s, lasers have been used for a variety of urologic procedures, most notably for lithotripsy, vaporization of the prostate, and incision of strictures. Current lasers used in urology are outlined here, and this section focuses on safety and technical considerations for lasers in the endoscopic OR. A thorough description of the mechanisms of laser function and their applications in urologic surgery is available in other chapters.

The three most common lasers used in the United States are holmium (Ho:YAG), thulium, and the green-light laser (KTP). Of these, holmium and KTP are more common. As mentioned above, dedicated laser scopes are available through Storz or Olympus, or the laser fibers can be deployed through regular cystoscopes. Filters can be attached to the scope to protect the camera from laser damage if specialized scopes are not used. Continuous flow sheaths are preferred for use with lasers.

***Technical considerations*** Laser units are typically mobile, mounted on rotating casters, and are moved from room to room as needed. They require a power source and the path of the electrical cable should be considered in room setup. Laser fibers are sterile and should have a dedicated place on the sterile equipment table. Because the laser fiber is long and thin, everyone who handles one should be mindful of controlling its whole length when it is not in use. This is especially true for the holmium laser, as its fiber is especially fine. We recommend the use of a wet sterile towel draped over the fiber to keep it in place. An additional towel may be placed on the lithotomy stirrup where the fiber crosses into the sterile field. This towel can be folded over the fiber to maintain its position while in use.

***Laser safety*** The laser produces an intense, highly directional beam of light. If directed, reflected, or focused upon an object, laser light will be partially absorbed, raising the temperature of the surface and/or the interior of the object, potentially causing an alteration or deformation of the material. A full awareness of the potential hazards and necessary safety standards associated with laser use is necessary, as the application of lasers in urology has increased dramatically in recent years. Laser safety and hazards cannot be completely described in this chapter; nevertheless, important aspects are covered and referenced for a more detailed reading. The reader can refer to http://www.laserinstitute.org/ for a comprehensive understanding of lasers.

***Laser hazards*** Lasers pose the greatest risk to the eyes and skin of OR staff. The precise effect varies with the frequency and intensity of the laser. Eye protection is particularly important when using lasers as all three of the commonly used laser types can damage eye structures. Energy from the holmium laser has a wavelength of 532 nm. Because this wavelength is in the visible spectrum, holmium lasers can cause severe retinal burns. Thulium and holmium lasers have wavelengths of 2013 nm and 2140 nm, respectively, placing them in the infrared portion of the spectrum. These lasers spare the retina but can damage the lens and the cornea. Skin is far less likely to be damaged by lasers because of the layer of dead keratinized cells. However, medical lasers do have the power to cause burns, photosensitivity, and darkening if contact is prolonged. Apart from bodily damage, lasers pose other hazards such as electrocution, fire, and asphyxiation related to damage or malfunction of the laser apparatus.

Staff must understand and comply with the mandatory safety regulations laid out by their health system and the device manufacturers. Because different lasers exploit different wavelengths of light, different eyewear is required for each laser. Glasses meant for protection from the green-light laser are not suitable for holmium, and vice versa. Appropriate warning signs must be placed prior to the procedure. Nursing staff should ensure that there is extra eye protection near the main entrance. This allows other personnel to enter during the procedure without risking injury. The patient's eyes and eyelids should be protected from the laser beam in a method deemed appropriate by the laser safety officer. Any change in the status of the laser must always be announced (e.g. active or stand-by) by the surgeon and repeated by the individual manually changing the laser settings. Prevention of injury is key as there is no first aid for laser eye damage. Any hazardous exposure to laser should be reported to hospital authorities.

Because of the potential hazards of working with medical lasers, various governing bodies have prescribed regulations and safety standards and best practice guidelines for their use. In the United States, Occupational Safety and Health Administration (OSHA) creates and enforces these guidelines. All laser manufacturers must comply with the standards outlined in ANSI Z136.3-1996/2011 of the American National Standards Institute. European equivalent standards are designated EN207/208/60825.

### Radiation

Interventional fluoroscopy is essential in endourology. Advancements in the field have led to more complex and time-consuming procedures, making protection from radiation even more important for the surgeon, staff, and patients. The hazards of radiation to the patient include immediate or delayed skin injury and a small but real delayed risk of cancer. Studies from percutaneous transluminal coronary angioplasty have estimated long-term cancer risk of 0.1% in men older than 60 years with exposure of 80 Gy/cm$^2$ (effective dose 20 mSv) [15]; the risk is estimated to be up to fourfold in children younger than 10 years. The exposure of OR staff during endourological procedures is significantly less than for patients, but because they are at risk for exposure regularly, proper containment is paramount [16, 17].

The recommendations for containment of radiation within the OR is a minimum of 2 mm of lead equivalent in walls. This requires 15 cm thick concrete or 25 cm thick brick or cinder block walls if lead is not used [16]. Personal protection equipment including articulated shielding, lead aprons, gloves, thyroid shields, and glasses must always be available in adequate numbers and sizes. The minimum recommendation in lead garments is 0.25 mm lead thickness for protection against scattered radiation, and 0.50 mm lead thickness for protection against direct radiation. There should be an easily visible indicator outside of the OR whenever fluoro is in use. We advise use of dosimeters by all staff for periodic monitoring of radiation exposure and many centers provide dosimeters on request. The principles of proper shielding, minimizing time and radiation, and maintaining proper distance from source are known by the acronym ALARA (as low as reasonably achievable). Guidelines and recommendations have been published by the National Cancer Society and the International Atomic Energy Agency (http://goo.gl/VfKmgZ).

## Patient handouts

In the age of shared decision-making, it is important for patients to have an adequate understanding of their disease, its treatment, and how to care for themselves after surgery. Verbal teaching with time for questions should be integrated into the patient visit at the time of diagnosis, but is not typically sufficient to ensure patient understanding. The use of diagrams or models alongside printed literature can fill the gaps left after consultation. Having an easily understood handout written in plain language encourages patients to develop a greater understanding of their condition and allows them to absorb information at their own pace. This aids in truly informed consent and creates opportunity for patients to ask more insightful questions about their disease. Patients may be directed to https://www.urologyhealth.org/educational-materials for peer-reviewed literature, frequently asked questions, and perioperative care information.

At the time of the initial consultation, the appropriate procedure is explained to the patient and any questions and concerns are addressed. Most often, patients want to know the length of the procedure and hospitalization, the amount of pain and its treatment, and how long the recuperation period will be. The literature provided to the patient at this encounter should describe their condition, explain the options for treatment including surgery, outline the necessary preoperative workup, and cover the basics of what to expect before and after the operation. Patient literature should also include a list of instructions that the patient must follow before surgery. This includes withholding food prior to the procedure, any site preparation that may be necessary, medications that should be withheld before the surgery, and any remaining preoperative workup. Important preoperative tests to perform for endoscopic lower tract procedures include a complete blood count, electrolyte panel, coagulation studies, urinalysis, and urine culture. If the urine culture is positive the patient should be treated preoperatively with appropriate antibiotics. Electrocardiogram and chest radiography are sometimes performed based on the patient's age and medical history. All of these tests should be reviewed the day of surgery. Preoperative handouts should also include day-of-surgery information, including the location of the medical center, the location of surgical check-in, maps for parking and navigation through the hospital, and relevant addresses and contact information.

Additional literature should be provided to the patient and their family or social support on the day of the procedure. Undergoing surgery is a stressful experience for patients and family, and any information provided in the perioperative period is quickly and easily forgotten. Because of this, handouts provided after surgery should complement the previously provided literature and include a brief explanation of the condition that required surgery.

## Introduction

Despite a wealth of information regarding outcomes for most minimally invasive surgical treatments (MIST) options for lower urinary tract symptoms caused by benign prostatic hyperplasia (BPH), there are limited studies regarding the best method of local anesthesia for prostate procedures. No "standard" exists with respect to the office-based anesthetic protocol.

During the past decade, as minimally invasive techniques have continued to proliferate and reimbursements for hospital-based procedures have diminished, reimbursements for office-based procedures have remained favorable. Physicians in private practice have increasingly sought to perform procedures in the office. Microwave procedures could be performed without intravenous analgesia [1]. Urologists also found transurethral needle ablation (TUNA) using radiofrequency energy and interstitial laser coagulation could be performed with local anesthesia in the office [2–4]. Similarly, prostatic urethral lift procedures (e.g. UroLift®) can be performed under spinal and local anesthesia in the office setting [5], and currently, urologists are performing and developing techniques for safe and comfortable laser ablation of the prostate in the office setting. Such a trend may change as reimbursement changes; nevertheless, an in-office procedure has a potential to be safer (in that only local anesthesia is used), more convenient and efficient for the patient. Such procedures are also less costly overall, saving on hospital/surgery center fees and professional anesthesia charges. Whether urologists continue to develop and advance in-office MIST remains to be seen. Urologic outcomes should be similar to procedures performed in the hospital or surgery center with full anesthesia or intravenous sedation. True evidence-based conclusions comparing procedures performed with anesthesia and anesthetic monitoring to those performed under local anesthesia in the office do not exist.

This chapter discusses the common pharmacologic agents that can be used as local anesthetics, and the application and techniques used to deliver local and regional anesthesia. The techniques used to anesthetize the prostate for MIST continue to evolve. It is hoped that the information presented will stimulate proper study for the development of improved local anesthetic protocols and techniques. Any local anesthetic protocol for the performance of MIST of the prostate in the office setting should have the following goals: (i) to provide satisfactory anesthesia such that the patient and surgeon feel comfortable with the performance of the procedure in the office setting; (ii) to safely administer the anesthetic so that proper patient monitoring requires nothing more than vital signs and observation; (iii) to minimize the risk of complications or bleeding that might interfere with proper performance of the procedure; (iv) to carry out the MIST in a fashion that is complete and not compromised by the use of local anesthesia instead of regional (i.e. spinal) or general anesthesia.

## Patient selection and preparation

In order to enhance the likelihood of patient acceptance and comfort, preoperative counseling is paramount. The experienced urologist should also develop the skill of patient selection, much like that in selecting patients for in-office vasectomy and cystoscopy. Patient size, prostate size, and patient comfort level with the office physical examination and preoperative counseling need to be taken into account. Patients should be counseled on the

likelihood that they will not be fully anesthetized such that they will not be numb to all feeling. Some discomfort should be expected but this should be mild and generally well tolerated. Time should be spent explaining the delivery technique of the local anesthetic so that patients know what to expect.

## Pelvic neuroanatomy

The following is a brief discussion of the relevant prostatic and urethral neuroanatomy. With a basic knowledge of genitourinary innervation, it is easier to understand which nerves can be appropriately targeted for prostatic and posterior urethral anesthesia.

The inferior hypogastric (pelvic) plexus receives both sympathetic (hypogastric nerve) and parasympathetic (pelvic splanchnic nerve) innervation. The plexus is a 4–5 cm long rectangle and its midpoint reaches to the tip of the seminal vesicles [6]. It runs on either side of the rectum, communicating behind the rectum and sending branches to encompass the vesical neck (Figure 143.1). The distal end of the pelvic plexus gives off branches to the posterior lateral aspect of the prostate, running in close association to the arterial and venous supply (neurovascular bundle) [7]. The nerves lie in the lateral endopelvic fascia near its junction with Denonvilliers' fascia [8]. The nerves then coalesce at the apex of the prostate at the 5 and 7 o'clock positions [9, 10]. Superficial branches innervate the urethral sphincter at the 3 and 9 o'clock positions, while deep branches are sent to the bulbourethral glands. As the cavernous nerves reach the penis, branches innervate the urethra at the 1 and 11 o'clock positions, while small branching fibers join the dorsal nerves of the penis [4, 6].

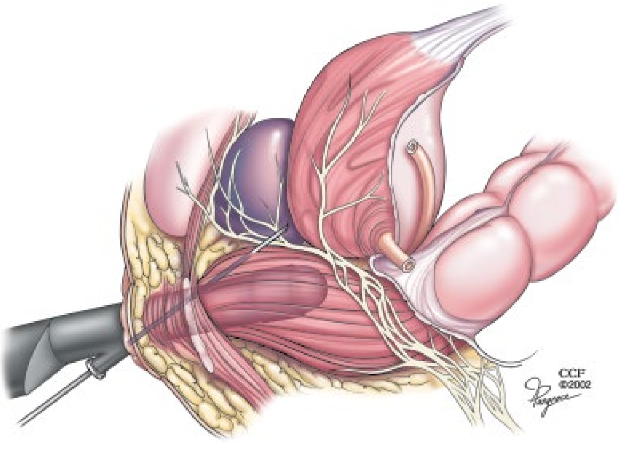

**Figure 143.1** Prostatic neuroanatomy. The inferior hypogastric (pelvic) plexus lies on either side of the rectum and its midpoint stretches to the tip of the seminal vesicles. *Source:* Cleveland Clinic, Ohio, USA. The pudendal nerve originates from Onuf's nucleus in the sacral spinal cord (S2–S4), leaves the pelvis between the piriformis and coccygeus muscles, and enters the greater sciatic foramen [11]. It then re-enters the pelvis through the lesser sciatic foramen and passes through the pudendal canal. Branches are sent off to the rectum (inferior rectal nerves), perineum (perineal nerve), and penis (dorsal nerve of the penis) [12]. The urethral sphincter has both autonomic and somatic innervations. Hollabaugh et al. performed a study of 12 fresh cadaveric dissections and confirmed the presence of an autonomic (pelvic nerve) and dual somatic (intrapelvic pudendal and perineal nerve) innervations of the rhabdosphincter [13]. From these descriptions it can be reasoned that a local anesthetic delivered anywhere from the seminal vesicles to the apex of the prostate should have some effect on sensory input from the prostate. Likewise, the rhabdosphincter could also be affected by nearby local anesthetics.

## Local anesthetic pharmacology

Local anesthetics act by inhibiting voltage-gated sodium channels that allow sodium ion influx into the nerve. This results in membrane stabilization and inhibition of neuronal action potential [14]. Amide local anesthetics are the most common class of anesthetics used by urologists. Allergic reactions are class specific, meaning that a person may have a hypersensitivity to multiple anesthetics in the same class [14].

The addition of epinephrine (1:200 000) can provide vasoconstriction. This will decrease blood flow to the injected area, decrease intraoperative bleeding [15], and causes a slower reabsorption/extended effect. Epinephrine should not be injected into areas that are supplied by end-arteries (fingers/toes, glans penis, nose, etc.).

Amides are common local anesthetics used in urology and include lidocaine, bupivacaine, and mepivacaine (Table 143.1). Lidocaine is the most commonly used local anesthetic and it is well known to urologists. It can be given as a 0.5% or 1% solution at a maximum dose of 3–5 mg/kg. The onset of action is 2–5 minutes and it has duration of action of 30 minutes to 2 hours [16]. A 0.5% solution provides 5 mg/ml, so an 80 kg person can receive up to 80 ml of a 0.5% lidocaine solution or 40 ml of a 1.0% solution. Lidocaine, when used without vasocontricting agents, shortens its own duration by dilating local vasodilation; this is contrast to bupivacaine and mepivicaine [17]. Bupivacaine has more than twice the duration of action of lidocaine, up to 8 hours. A full dose of bupivacaine is 1–2 mg/kg, or 3 mg/kg in combination with

**Table 143.1** Common local anesthetics used in urology.

| | Concentration (%) | Dose (mg/kg) | Onset (min) | Duration (h) |
|---|---|---|---|---|
| Lidocaine | 0.5–1.0 | 3–5 | 2–5 | 0.5–1 |
| Mepivacaine | 0.5–1.0 | 4 | 3–5 | 1–1.5 |
| Bupivacaine | 0.25–0.5 | 1–2 | 2–10 | 2–4 |

*Source:* From Berde and Strichartz [14], with permission.

epinephrine. A 0.25% solution provides 2.5 mg/ml of bupivacaine, so an 80 kg person can receive up to 64 ml of a 0.25% solution or up to 32 ml of a 0.5% solution. There is a known toxicity of ventricular arrhythmias/cardiac arrest with overdosing [16]. Mepivacaine is dosed at up to 4 mg/kg with a quick onset of action of 3–5 minutes and a duration of action of 45 minutes to 1.5 hours. A 0.5% solution provides 5 mg/ml of mepivacaine, so an 80 kg person can receive up to 64 ml of a 0.5% solution or up to 32 ml of a 1.0% solution. Toxicities include central nervous system (CNS) side-effects/seizures and bradycardia/heart block [16].

In general, toxicities can occur if an overdose of anesthetic is given, or if the anesthetic is mistakenly injected into the vasculature. Proper infiltrative techniques, including a fundamental knowledge of the surrounding anatomy and aspiration prior to injection of the anesthetic, help to avoid these complications. CNS side-effects include a spectrum of symptoms from tinnitus and metallic taste in the mouth to seizure activity. Cardiovascular side-effects range from bradycardia, atrioventicular block, and ventricular arrhythmias to cardiac arrest [16]. Allergic reactions can occur at any dose if there is a hypersensitivity, and can cause anything from hives to overt anaphylactic shock. Amide anesthetics are metabolized by the liver and excreted by the kidneys, so the dosage should be decreased in patients with either liver or kidney failure [14]. For the purpose of local anesthetic for MIST of the prostate, the doses needed for a reasonable block seem to be well below anything close to the maximum dose, making toxicities very unusual. Lidocaine is clearly the most commonly used agent in the office setting.

## Oral supplementation

Many office-based MIST protocols for the prostate involve preoperative oral medications to mitigate pain, anxiety, and bladder symptoms. As such, oral pain medicines, sedatives, and antianxiety medications are often considered along with anticholinergics. These preoperative "cocktails" are developed by word of mouth, with urologists sharing experiences as they bring a MIST into the office.

The use of oral medications, while likely very beneficial to patients, has not been studied in a way that allows "best practices" to be established. It can be safely said that the preoperative medications used are generally very well understood by urologists, who use similar medicines in the day-to-day management of their patients (Table 143.2). Any study of local anesthesia for MIST of the prostate will be hampered by the added effects of these oral medications. If a local anesthetic technique is capable of working alone for a specific MIST, it must be proven as effective without oral supplemental agents. Nevertheless, preoperative oral medications that add to patient comfort and safety are clearly appropriate.

If prescribing oral sedation, urologists should be aware of any state medical board or society regulations for office-based surgical procedures. They should at least be certified in Basic Cardiac Life Support (BCLS) or Advanced Cardiac Life Support (ACLS) with course completion/recertification within 2 years.

## Topical urethral anesthesia

Prior to flexible cystoscopy being available, urologists routinely performed rigid diagnostic cystoscopy in the office with or without an anesthetic gel, such as 2% lidocaine. There is no question that a significant number of patients found the exam very uncomfortable and rarely would any patient suggest there was no discomfort at all. Urologists experienced with rigid cystoscopy understood that most of the discomfort tended to occur as the scope traversed the membranous and prostatic urethra, straightening the bulbous and proximal urethral anatomy. Patients reflexively resist cystoscopy by tightening the perineal musculature and membranous urethra. However, once in the bladder, patients would often relax with the words "the worst part is over." The diagnostic cystoscopy could then be completed in most instances.

Again, patient selection was still very important in enhancing the odds of a successful procedure.

**Table 143.2** Oral medications for minimally invasive prostate therapy.

| | Dose (mg) | Onset (min) | Duration (h) | Toxicities |
|---|---|---|---|---|
| **Benzodiazepines** | | | | |
| Diazepam | 5–10 | 45–90 | 2–24 | Respiratory, seizures, anaphylaxis |
| Lorazepam | 1–2 | 45–90 | 6–12 | Respiratory, seizures, anaphylaxis |
| Alprazolam | 0.25–0.5 | 60 | 6 | Respiratory, seizures, anaphylaxis |
| **NSAIDs** | | | | |
| Napoxen | 220 | 30–60 | 7–12 | Gastrointestinal, bleeding, renal |
| Ketorolac | 10 | 30–60 | 4–6 | Gastrointestinal, bleeding, renal |
| **Narcotics** | | | | |
| Hydrocodone/acetaminophen | 1–2 tabs (5/500) | 10–30 | 4–6 | Respiratory, constipation |
| Oxycodone/acetaminophen | 1–2 tabs (5/325) | 10.30 | 4–6 | Respiratory, constipation |
| **Anticholinergics** | | | | |
| Hyoscyamine | 0.125 | 2–3 | 4 | Gastrointestinal, urinary retention, dry mouth |

Intraurethral lidocaine was first described in 1949 by Haines and Grabstald in 250 patients undergoing cystoscopy. Lidocaine acts on suburothelial nerves to inhibit impulse transmission [18]. Although lidocaine gel has been used for decades for cystoscopy in males, the proof that it works well as a local anesthetic is lacking. Stein et al. showed no benefit of lidocaine gel compared to a water-based lubricant for rigid cystoscopy in males in a prospective randomized controlled double-blind study [19]. Dwell time for the lidocaine was 5–10 minutes. In an effort to see if dwell time was insufficient, Goldfischer et al. performed a similar study using 30 ml of 2% lidocaine gel with a dwell time of 20 minutes before cystoscopy, comparing this to water-soluble lubricant. They found a slightly significant difference in patient-perceived pain scores [20]. Both lidocaine gel and lubricant-only groups had discomfort and perhaps the difference was not clinically significant, as urologists could not differentiate who received lidocaine and who did not. Another study by Eggersmann et al. demonstrated in a randomized, double-blind placebo-controlled study that pain –relieving effects of lidocaine required an exposure time of greater than 10 minutes. Further studies showed no added utility in dwell time greater than 15 minutes [21]. This being said, there are numerous modern studies suggesting that 2% lidocaine works no better than water-soluble lubricant for flexible cystoscopy in the male [22–27]. This is likely secondary to the difficulty to efficiently block afferent pain signals of the entire urethra secondary to the complex innervation of the rhabdosphincter.

It is therefore of interest that virtually every publication of in-office MIST of the prostate discusses some form of topical lidocaine instillation transurethrally. It is likely that very little lidocaine is actually delivered to the prostatic urethra or is able to dwell there. Normal retrograde urethrograms seldom show much contrast in the prostatic urethra. Some urologists add cooled 2% lidocaine solution instilled through a catheter to their MIST protocols. Though intravesical lidocaine has been used as a local anesthetic for bladder procedures, it has not been suggested as a prostatic anesthetic [28, 29]. However, intravesical chilled lidocaine may mitigate discomfort during the bladder distention that is associated with cystoscopy.

Until studies are done comparing procedures performed with topical lidocaine to those performed without, the true value of topical lidocaine is open for discussion in MIST protocols. That said, all catheter-based technologies (i.e. transurethral microwave thermotherapy of the prostate (TUMT)) call for some form of lidocaine gel instillation before placing the catheter. Likewise, most technologies for MIST involving endoscopes call for lidocaine topical gel as an added local anesthetic. In general, 10–30 ml of 2% lidocaine gel is instilled for a 5–20 minutes dwell time prior to the particular procedure. Cooling the gel may aid in the comfort of delivery [30]. There should rarely be any complication from transurethral lidocaine gel and system levels of lidocaine are not seen [31]. If indeed lidocaine gel is nothing more than a placebo, it may be a valuable placebo. Both patients and urologists are comforted by the idea of delivering an anesthetic through a "painless gel" rather than a needle, which is what is required for any of the prostate blocks that are discussed below. The current evidence, however, suggests topical local anesthesia to the urethra and prostate for MIST procedures probably is marginal in its true value, and clearly more expensive than water-soluble lubricant.

## Prostate blocks

MIST options for the prostate that involve high-powered TUMT or rigid cystoscopy with either TUNA, interstitial laser energy, or laser evaporative/ablative techniques require more than simple topical lidocaine to the urethra. These endoscopic procedures must be performed with clear visualization of the prostatic urethra for optimal performance. Any sudden motion of the patient can jeopardize the procedure because of bleeding or patient discomfort. As such, all procedures were originally developed under general, regional (spinal) or intravenous sedation. Urologists experienced with prostate blocks for prostate biopsy and transurethral needle injection technique began to develop techniques to block the posterior urethra and prostate in such a way that these procedures could be performed in the office setting. They were motivated to develop their own in-office protocols in the hope of saving overall costs without diminishing physician reimbursement. Standard techniques developed after evidence-based studies have not been established. Local anesthesia involving prostate blocks for MIST are still evolving. There are no studies comparing different in-office local anesthetic techniques for MIST. There are, however, articles on local prostate block for prostate procedures and much has been written on local anesthesia for prostate biopsy.

With regard to prostate biopsy, preprocedure anxiety is associated with exaggerated pain perception throughout the procedure. Similarly, pain during probe insertion has a positive correlation with pain during biopsy. Unsurprisingly, younger patients are more susceptible pain due to low anorectal compliance, higher pretest anxiety, and higher sphincter tone. The apex of the prostate is most painful site of biopsy secondary to rich somatic nerve innervation to the mucosa below the dentate line [32]. Moffat injected 10 ml of 1% lidocaine with epinephrine into each lobe of the prostate of 18 patients via a digitally guided transperineal route using a 20G spinal needle [33]. Then, using nothing more than topical lidocaine per urethra, he was able to dilate the urethra to 30 Fr using sounds, and he then performed transurethral resection of the prostate (TURP) using a 28 Fr resectoscope sheath. All procedures were performed in the operating room with anesthesia monitoring. Supplemental sedation was required in 10 of 18 patients. Remarkably, 8 of the 18 patients had no intravenous sedation and no preoperative medications were given. Although this technique was seldom used, the fact remained that injection of lidocaine directly into the prostatic parenchyma must have anesthetic value if it allowed for a full TURP.

Orandi followed up on this in 1984, describing multiple endoscopic procedures, including TURP, performed using transurethral lidocaine injected into the prostate and bladder neck via a specially devised endoscopic needle [34]. Supplemental oral and parenteral medications were used in his cases. The publication was presented as a “cost reducing idea.” The technique similarly did not catch on. In 1993, Hugosson et al. published their results with transurethral incision of the prostate under local anesthesia [35]. Mepivacaine was injected transurethrally under direct vision into the bladder neck and posterior prostate to allow performance of a 6 o’clock incision of the prostate to treat men with lower urinary tract symptoms. The patients apparently received no supplemental preoperative or intraoperative medications. Twenty-eight of 30 patients claimed they would agree to the same procedure if another were needed. These examples suggest that local prostate block can allow for major endoscopic prostate procedures and that the block itself is responsible for pain control rather than oral or parenteral supplements.

Pain from prostate biopsy generally originates from the prostatic capsule. The prostatic plexus surrounds the capsule and has extensive autonomic innervation [32]. Prostate blocks did not become common place, however, until the development of transrectal ultrasound-guided biopsy and ultrasound-guided periprostatic and intraprostatic blocks. Prior to transrectal prostate ultrasound, digitally guided transrectal biopsy of the prostate was routinely performed with acceptable patient tolerance using no anesthetic. As template biopsies were developed in the prostate specific antigen (PSA) era, along with saturation biopsy, local anesthetic techniques developed and showed that transrectal ultrasound-guided lidocaine for periprostatic block at the prostatic base could mitigate the discomfort of the biopsy [36–38]. Subsequent studies suggested that ultrasound-guided transrectal lidocaine at the apex worked just as well or better [39–42]. Transrectal intraprostatic injection of the prostate has been suggested as better than a periprostatic block for pain control [43]. Finally, a periprostatic and intraprostatic combination block may work best of all for transrectal ultrasound-guided biopsies [44–46].

Armed with the knowledge that prostatic block could work in the operating room for transurethral resection procedures and that transrectal block worked well for prostate biopsies, urologists are adapting these technologies for office-based MIST of the prostate.

## Transrectal block for office-based minimally invasive treatment

Although most urologists are aware of and familiar with transrectal ultrasound-guided periprostatic and intraprostatic blocks for prostate biopsy, it should not be assumed that this will be optimal for transurethral MIST of the prostate. While it is traditionally thought to be well tolerated by most patients, some literature suggests between 65% and 90% of patients report discomfort during the procedure [47]. The largest criticism of transrectal periprostatic block is its inability to relieve pain from probe insertion. In addition, the incidence of febrile episodes after transrectal prostate biopsy may be increasing. Nam et al. found hospital admission rates after transrectal ultrasound-guided biopsy of the prostate increased fourfold from 1996 to 2005; 72% of these were admissions for infection [48]. Efforts should be made to ensure the rectal vault is empty of stool prior to biopsy. Urologists should administer prophylactic antibiotics, such as those recommended by the American Urological Association better practice guidelines for antimicrobial prophylaxis.

The standard technique calls for ultrasound-guided injection of at least 5 ml of 1% lidocaine into the fat plane seen laterally at the base of the prostate, between the seminal vesical and rectum. On sagittal view, this appears as a “triangle,” referred to by Jones as the “Mount Everest sign” [36]. Each side must be injected. Alternatively, or at the same time, 5 ml of 1% lidocaine can be injected into the periapical fat, deep and lateral to the apex, between the prostate and rectum. On sagittal view, infiltration of anesthetic can be seen to separate a tissue plane that courses towards the base [39, 42]. The article by Berland and Jones in e-medicine fully describes transrectal periprostatic blocks and is a useful website (http://emedicine.medscape.com/article/459599-overview). When local anesthetic injections are administered too laterally (i.e. lateral to the tip of the seminal vesicles), pain relief is ineffective secondary to distance from neurovascular bundle. Using the same ultrasound-guided technique, intraprostatic anesthesia can be delivered by injecting 10 ml of lidocaine in increments in 2–3 sites within each lobe of the prostate from apex to base [43]. In addition, the use of combined intrarectal local anesthesia with periprostatic nerve block helps to improve pain control during prostatic biopsy and should generally be performed in conjunction with periprostatic anesthesia delivery [44].

Although none of the transrectal local lidocaine blocks were developed for procedures other than biopsy, urologists have adapted them for MIST. Kedia used a digitally guided transrectal lidocaine block to perform interstitial laser coagulation of the prostate [49]. Other than transurethral lidocaine (a liquid and gel), patients received no oral or parenteral medications other than antibiotics. Turk has performed Evolve™ diode laser transurethral resection procedures in the office without any intravenous sedation, assisted in part by transrectal ultrasound-guided periprostatic block [50]. However, it should be noted that he now favors a transurethral prostatic block. Meyer has performed many Prostiva™ radiofrequency procedure TUNA in the office using a transrectal periprostatic block with lidocaine from apex to base on each side, although oral analgesics and sedatives were also used. He claims not to have terminated or abbreviated any procedures in over 300 cases (personal communication).

With more contemporary TUNA treatments that use radiofrequency-produced convective steam (i.e. Rezum), it is important to not violate the prostate capsule with a needle. During TUNA with Rezum, this steam penetrates the interstices and is confined in the prostatic capsule; a perforation of the capsule with a transurethral prostate injection or posterior prostate capsule may theoretically affect heat confinement. Transrectal block should be done with ultrasound guidance and near the tips of the seminal vesicles [51]. TUMT procedures were also done with a transrectal block; transrectal ultrasound (which is needed to position the treatment catheter) is used to guide the lidocaine for a prostate block prior to the placement of the treatment catheter. Alcohol ablation or transurethral ethanol ablation of the prostate (TEAP) has been described in the literature utilizing a periprostatic block with oral or intravenous sedation. Similarly, the Rezum radiofrequency system for BPH has been described as having the advantage of being capable of being performed as an outpatient under local anesthesia [52]. Many TUMT procedures can be performed without a formal prostatic block. Members of our groups are performing laser procedures (Evolve and GreenLight) using transrectal ultrasound-guided periprostatic and intraprostatic blocks with lidocaine. Good functional outcomes were presented at our State Urological Society Meeting [53].

## Transperineal block

Transperineal block, although likely least utilized today to provide local anesthesia to the prostate, has the potential for resurgence if in-office MIST procedures continue to develop. Over the last decade or so, there has been an increased incidence of infection and quinolone-resistant flora with a concomitant increase in sepsis rate as high as 5%, thereby renewing the debate of optimal anesthetic delivery, especially in the context of prostate biopsy [54]. Unlike the transrectal technique, the risk of infection should be lessened by allowing for a proper skin preparation and directing the needle to avoid contamination from the rectal mucosa.

A modern technique has been nicely described by Issa et al. [3] and Cohen and Steiner [55]. The patient is placed in the dorsolithotomy position with the perineum prepped and draped. A 27G needle may be used to anesthetize the entry site in the perineum above the perineal body. A 22G spinal needle (3.5 inches long) is attached to a 20 ml Luer Lock syringe containing the anesthetic (i.e. 1% lidocaine). The needle is directed into the midline, deep to the apex of the prostate under transrectal digital guidance. The anesthetic solution is infiltrated, defining a plane between rectum and prostate that may be palpated as the rectum is elevated from the prostate. At least 10 ml of the anesthetic solution is injected deep to the prostate on the right and then the left, from apex to base. This should deliver anesthetic levels similar to transrectal anesthetic technique. The needle need not be removed from its insertion site as injections occur, as aspirating periodically ensures that the injection is not into venous spaces. Interstitial laser coagulation (ILC) therapy has been successfully performed without the need for intravenous sedation using the transperineal periprostatic block [3].

A simple technique for transperineal digitally guided block of the urethrosphincteric region has been recently described by Al-Hunayan et al. [56]. They injected 5–10 ml of lidocaine into the region just caudad to the apex of the prostate, above the rectum on each side of the midline. Their technique showed improved comfort with rigid cystoscopy over lidocaine per urethra (Figure 143.2). Likewise, TUNA of the prostate has been similarly performed [57].

As mentioned earlier, TURP has been performed using a transperineal intraprostatic block without the need for intravenous sedation [33]. The transperineal route could also be very easily used to perform intraprostatic injection of anesthesia for MIST. Using an anesthetic agent that contains epinephrine could potentially mitigate bleeding for transurethral procedures. Bolat et al. examined periprostatic block against transperineal prostatic block in a prospective randomized trial and found lower visual analog scores (VAS) in those patients receiving 10 ml 2% prilocaine in a transperineal block compared with intrarectal lidocaine gel followed by 10 ml 2% prilocaine periprostatic block [58]. Though not studied specifically for MIST, this route also would have an added advantage over the transurethral intraprostatic injections in that the prostatic lumen could be avoided by targeting the needle laterally, thus minimizing potential bleeding from the needle entrance site in the prostatic urethral lumen. Clearly, if the procedure is planned in the office, the MIST modality itself should already be proven to minimize the risk of bleeding.

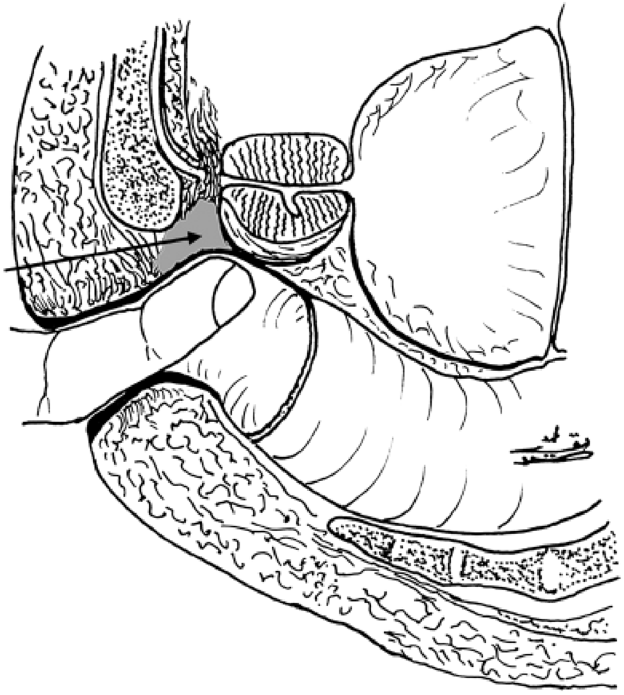

**Figure 143.2** Digital guidance for transperineal prostatic block. This depicts the infiltration of lidocaine (gray area indicated by arrow) in a location bounded by the rectum posteriorly, the rhabdosphincter anteromedially, and the apex of the prostate superiorly. *Source:* Al-Hunayan A, Kehinde EO, Shihab-Eldeen A et al. An assessment of the clinical utility of transperineal urethrosphincteric block (TUSB) in outpatient rigid cystoscopy: a single-blind, randomized study. *Int Urol Nephrol* 2009;41:47–53. ## Transurethral prostate blocks

Since originally described by Orandi, transurethral prostate blocks have been reinvented by urologists in order to perform local MIST of the prostate in the office setting. The technique can easily be performed by any urologist using a flexible injection catheter passed via the cystoscope. The patient is prepared for rigid cystoscopy in the lithotomy position. Oral agents, both analgesics and sedatives, can be helpful. The cystoscope is passed and the prostatic lumen and bladder are examined. An injection catheter (Bard Contigen, Cook Urologic, Storz reusable, etc.) can then be used to inject 3–5 ml of an anesthetic solution (e.g. lidocaine) into the bladder neck at the 5 and 7 o'clock positions. The cystoscope is then moved distally to view the prostatic lobes, which are then anesthetized by injecting at the 3 and 9 o'clock positions with additional lidocaine. Injections can be repeated in different areas if needed for longer or larger glands. Patient selection is important. The transurethral block also avoids the rectum and its potential for infection. Using this technique, urologists have performed ILC, TUNA, and laser prostatectomies, including GreenLight and diode laser prostatectomies. TUMT time can be diminished by transurethral mepivacaine with epinephrine, with improved comfort [15]. These procedures have been performed in the office without the need for an intravenous line or special monitoring, other than close observation and periodic measurement of vital signs.

Published studies regarding outcomes are lacking. Though members of our group have used this technique, they have found bleeding occasionally problematic for laser ablation procedures and now prefer the transrectal technique previously mentioned.

## Pudendal nerve block

Pudendal nerve block is mentioned as it may have endourologic application for the lower urinary tract, and it is an anesthetic that can be delivered by the urologist. Mahmood Hai (Dearborn, MI, USA) probably has the world's greatest urological experience with pudendal nerve block in men, a technique he developed from his knowledge of pudendal blocks in women. In his surgery center he has performed outpatient photoselective vaporization of the prostate on over 1000 patients. His technique involves a transperineal approach. Two 20G 12 cm disposable spinal needles are attached to 20 ml syringes loaded with a 0.5% lidocaine solution. For right-handed urologists, the left index finger is inserted rectally to identify the landmarks; the ischial tuberosity, ischial spine, and sacral spinous ligaments. The needle is inserted perpendicular to the skin about 2.5 cm posteromedial to the ischial tuberosity. The needle is slowly advanced through the ischial rectal fossa towards the ischial spine, guided by the rectal finger. As the needle hits the spine, it is pushed posterior to it by the guiding finger. This places the bevel of the needle at the beginning of Alcock's canal. After attempted aspiration in two planes to make sure the needle is not in a blood vessel, 5 ml of the solution is injected. In most instances, the wheel produced can be palpated by the rectal finger. The needle is advanced about 0.5 cm and the remaining 5 ml are injected. The needle is withdrawn and firm pressure is applied over the area by the rectal finger for 1–2 minutes. A similar procedure is done on the opposite side. The anesthetic should be effective within 5 minutes and photoselective vaporization of the prostate can be started.

This form of anesthesia is not one that should be considered in the office setting without an intravenous line and proper monitoring. There is a potential for bleeding and nerve damage, as can rarely occur with any regional nerve block. Dr. Hai does have an intravenous line for sedation, monitored by an anesthesiologist. Nevertheless, it is worthwhile being aware of this technique as it represents a locoregional anesthetic which urologists can and are being trained to perform. Specifically, when discussing prostate biopsy, when combined with periprostatic nerve block, it has demonstrated statistically better pain control throughout probe insertion, biopsy punctures, and up to 1 hour after biopsy [59]. In one prospective study, unilateral pudendal block is as efficacious as intrarectal lidocaine with periprostatic blockade in pain reduction for both probe insertion and biopsy punctures [60]. More study will be needed before we know the true risk-to-benefit ratio compared to other anesthetic techniques.

## Conclusions

This may be a new era in urologic practice; treating more patients in the office with MIST of the prostate. As technologies evolve, so will the consensus of "best practice" regarding office-based local anesthesia. Studies that compare one anesthetic technique to another are sorely lacking. The potential for tremendous cost savings still exists if hospital and anesthesiology charges can be avoided by office-based therapy. Office-based therapies, however, must be proven to be just as effective with comparable long-term result. Urologists interested in pursuing office-based procedures under local anesthesia should realize that the information presented in this chapter will hopefully be dated in 5 years, as more outcome and comparative studies are done so that evidence-based recommendations can be made on the "best practice" of office-based anesthesia for the MIST of the prostate. It is likely that combining the techniques described in this chapter will result in improved local anesthesia for MIST of the prostate. Finally, without question, new technologies and techniques will continue to arise to treat lower urinary tract symptoms due to BPH. Office-based therapy has a great potential to provide for major cost savings as long as the urologist finds it economically viable to pursue such care in the office. Regardless, all urologists should be aware of the importance of minimizing anesthetic risks and cost for MIST of the prostate. Local anesthetic techniques may diminish anesthesia needs, time of recovery, and costs.

These cost savings may also be realized in the hospital or ambulatory surgery center setting. Such techniques might be applicable to more invasive hospital-based procedures, such as TURP in high-risk individuals or the very elderly, where close anesthetic monitoring is always required. The anesthetic risks may possibly be diminished by the use of local anesthetics. Similarly, though MIST of the prostate may be easy to perform in the office, caution and proper monitoring are always needed in high-risk or very elderly patients. Judgment is always required in selecting candidates for office-based MIST of the prostate using local anesthesia.

## Introduction to lasers

In his publication on quantum theory in 1917, Albert Einstein postulated the existence of extremely focused light beams [1], but it was another 43 years before the first commercially available laser became available, as published by Maiman [2]. The acronym LASER was created by Gould in 1957; it stands for laser amplification by stimulated emission of radiation [3]. In simple terms, a laser is a parallel light of a specific wavelength and direction [4]. Immediately after its first description, manifold lasers were developed and were widely used in many fields of medicine. Most of them did not stand the test of time, however, and the unsuccessful clinical application of laser devices led to a general decline in their use during the 1980s.

Ten years later, an improved understanding of laser principles provided better knowledge that led to the selection of appropriate lasers for specific medical applications [3–7]. With the development of lasers with many different wavelengths and qualities, various laser systems that could be used to treat urological conditions were developed. This chapter reflects the cumulative understanding of several different urological surgeons on the most widely used laser systems at this time.

An important facet of the clinical application of lasers is the optimization of the absorption process of light energy in tissue, with the knowledge that laser radiation is a directed light of a narrow bandwidth with specific effects. Each laser is synonymous with a single color or electromagnetic wavelength, and each laser can be derived from many wavelengths of the invisible and visible electromagnetic spectrum [8].

## Generation of a laser beam

Laser light is created by a quantum mechanical principle of "stimulated emission" of radiation in an excited state (active media: gas, crystal, glass, dye). Excitation of the laser medium can be achieved in various ways (e.g., excitation by photons from a flashlamp). Some of the excitation photons are absorbed by the active medium, leading to an excited state [4]. According to the theory of spontaneous emission, these excited states return to the ground state, statistically releasing a photon at a characteristic wavelength. If these spontaneously emitted photons hit another excited state of the same excitation energy, it stimulates the excited ion to return to the ground state by emitting a further photon with the same wavelength and the same direction of propagation and the same phase. This is called stimulated emission of radiation (Figure 144.1) [4–7]. The emitted wavelength is characteristic for the optically active components of the laser medium [4].

To achieve controlled excitation of the laser medium, it is embedded into an optical resonator, a set of mirrors within the optical axis of the laser medium that redirect emerging photons into the laser medium for further amplification. One of the resonator mirrors has a reflectivity at the laser wavelength of nearly 100% (high reflector) and the other one is partially transparent to allow laser radiation to exit from the resonator (output coupler). Laser radiation is emitted from the resonator in a continuous wave or pulsed manner depending on the construction of the laser device (e.g. excitation source, characteristics of the laser medium) or the presence of additional optical elements, such as a Q-switch [4].

Q (or Quality)-switching is a technique to generate short, high-peak, powerful laser pulses by modulating the cavity Q-factor (cavity loss) of the laser resonator. This comprises an optoelectronic shutter that is embedded within the laser resonator, which is periodically opened and closed. When it is closed (low cavity Q-factor), stimulation of emission is suppressed, but the population inversion reaches a large value due to the ongoing excitation process. When the shutter opens (high cavity Q-factor), spontaneously emitted photons start oscillating within the resonator, leading to an avalanche of stimulated emission. The larger the population inversion, the higher the Q-switch pulse peak power. The Q-switch pulse terminates with depletion of the population inversion [4].

Second harmonic generation (SHG) is a second-order nonlinear process used to convert a given laser (used in the potassium titanyl phosphate (KTP) laser) to half of its fundamental wavelength (second harmonic). It comprises a nonlinear crystal that needs to be carefully matched with the fundamental laser wavelength. Sufficient power density of the fundamental laser and exact alignment of the nonlinear crystal with the direction of propagation is required to generate second harmonic photons, which are double in frequency and/or half in wavelength [4].

In diode lasers, a semiconductor laser diode is used to generate laser radiation. The semiconductor material defines the wavelength. Electrical current flow is used to stimulate the semiconductor, which emits laser radiation after exceeding the threshold. Diode laser systems achieve a high electrical-to-optical energy conversion efficiency [4].

In contrast to diode lasers, other commonly used laser systems (holmium, thulium, GreenLight) utilize a crystal as the laser medium. In these laser systems the active laser ion is doped into the yttrium–aluminum–garnet (YAG) crystal that serves as a carrier for rare earth material defining laser characteristics. The widespread use of the YAG crystal is rooted in its physical properties. Crystals with garnet structure offer three crystallographic sites of different size and geometry, $\{C_3\}(A_2)[Al_3]O_{12}$, that are suitable for doping with optically active transition metal and rare earth metal ions. YAG is isotropic and has a broad range of spectral transparency. The YAG crystal also offers excellent mechanical and thermal properties. It is easy to grow following the Czochralski technique, which involves growing single crystals from their melt. During the growth process, the molten material is kept in a heated crucible. A seed crystal is lowered from above until it reaches the melt surface. The crystal boule is grown by pulling the seed crystal slowly upwards under continuous rotation [4–7].

For these reasons the YAG crystal is the material of choice for a variety of solid-state laser materials. By replacing a percentage of the yttrium ($Y^{3+}$) ions at the crystallographic C-position (doping) with three valent rare earth ions such as neodymium ($Nd^{3+}$), holmium ($Ho^{3+}$), thulium ($Tm^{3+}$), or erbium ($Er^{3+}$), optically active solid-state laser materials may be created. Under excitation, these crystals have the ability to amplify their own fluorescence light by stimulated emission of radiation [4–7].

## Delivery of laser radiation

### Laser fiber design

Optical fibers deliver laser radiation to the target safely and efficiently, although several issues have to be resolved. Laser radiation has to be coupled from the generator to the fiber and transported within the fiber to the desired point of application [4].

A laser fiber includes a circular fiber core and two or more levels of fiber cladding clasped around this core. Laser radiation is delivered through the circular fiber core, whereas the adjacent layer provides entrapment of laser radiation within the core and the remaining layers conserve fiber integrity [1, 6]. The optical core is made from silica. Standard silica material is used effectively for visible light, but the transmission of 2 μm radiation by flexible silica laser fibers, as in holmium and thulium lasers, requires purified low hydroxide (OH) silica to eliminate power loss during the delivery due to energy absorption in the $OH^-$ ion [6].

To suppress leakage of laser radiation, the core is surrounded by an optical cladding made from a transparent material of a lower refraction index. Fluorine-doped silica cladding is considered the primary choice for high-quality fiber applications. Less flexible fluoroacrylate cladding (TECS) is used for fibers to transmit shorter wavelength and low-power applications [5].

To launch laser radiation into an optical fiber, a focusing lens with a receptacle for the fiber connector is necessary. Connecting the fiber to the laser generator is critical for energy transmission [5]. A slight deviation of the focal point of the fiber coupler lens leads to laser radiation absorption by the connector, which guides the laser fiber to the coupler lens. Thus it will result in heating of the connector. At sufficiently elevated power levels, the focused laser beam will melt and vaporize, resulting in destruction of energy transmission [4].

### Types of fiber endings

Independently of the fiber type, the laser beam is delivered through the optical core of the fiber [4–7].

#### Side-firing fibers

In side-firing fibers, the reflection of the laser beam is achieved by an oblique surface at the fiber tip where the radiation is reflected sideways either by total reflection of the beam on a core–air interface or an additional reflective coating. This deflects the laser beam toward the tissue at an oblique angle of about 70°, which is provided by the physics of total reflection at an internal glass–air surface. By sweeping the beam and changing the distance between fiber tip and tissue surface, coagulation as well as vaporization can be achieved. The pitfalls of side-firing fibers are the limited lifespan due to exposure to heat that is generated by carbonization at the laser beam output [6], leading to fiber damage and consequently to loss of efficacy [5, 9]. However, continuous flushing of the beam exit with cooler irrigation fluid alleviated this effect as designed in the MoXy™ fiber. By increasing the optical core diameter and the introduction of liquid cooling as well as a metal capping of the fiber tip, the lifespan of the side-firing fiber seems to be increased [10]. Although it is generally plausible to manufacture a MoXy-type side-firing fiber for all laser systems, this design is currently applied only with the GreenLight XPS™ system [4].

#### End- or front-firing fibers

Laser radiation discharges from the tip into the tissue by rapid heating of the tissue in a very small tissue volume. Tissue effects such as vaporization and disruption can be achieved.

#### Twister fibers

Another approach called twister fiber is used for contact laser vaporization, as introduced by Biolitec for its laser system. The Biolitec laser uses a wavelength at which water is included as a chromophore. As a result, in front of the fiber tip a steam bubble is created, within which vaporization is achieved; vaporization is also created by the secondary heated button-shaped fiber tip [4]. A near-contact technique is required.

## Pulsed and continuous wave lasers

Laser radiation is emitted from the resonator in a continuous wave (cw) or pulsed mode depending on:

- the laser device (excitation source, characteristics of the laser medium) and
- the presence of additional optical elements, such as a Q-switch.

Holmium lasers are normally excited by flashlamps, which restricts the repetition rate due to heat accumulation in the laser crystal. In contrast, Tm:YAG lasers may operate in a cw-mode if excited by a laser diode. Pulsed holmium lasers create large pulsating steam bubbles in the irrigant surrounding the tip of the laser fiber, whereas the bubbles are much smaller for cw-mode lasers (Figure 144.2a,b). For the holmium laser, the lifetime of the steam bubble corresponds to the duration of the laser pulse (~500 μs) which is too short to be visible in video transmission during endoscopic procedures [8].

The expanding steam bubble is used in holmium laser enucleation of the prostate (HoLEP) for the separation of the adenoma from the peripheral zone. Coagulation is achieved by the heat within the steam bubble. In contrast, thulium lasers constantly support a steam bubble between the fiber tip and tissue. This bubble provides the optical contact for the laser radiation into the tissue. The constant steam bubble follows the fiber movement and the cw-mode thulium lasers allow smoother incisions in soft tissue, which is considered to be advantageous in urologic surgery. Accuracy, power efficiency, and minimal collateral damage are reported with the cw mode rather than the pulsed mode of the holmium lasers [8].

However, the cw mode is disadvantageous for the thulium laser's applicability for lithotripsy, since the required pulse peak mode for lithotripsy is not available in the cw mode of this laser [8, 11].

## Light–tissue interactions

The principal light–tissue interactions comprise reflection, scattering, re-emission, and absorption by tissue chromophores. Light distribution and absorption affect the optical penetration in a wavelength-dependent manner.

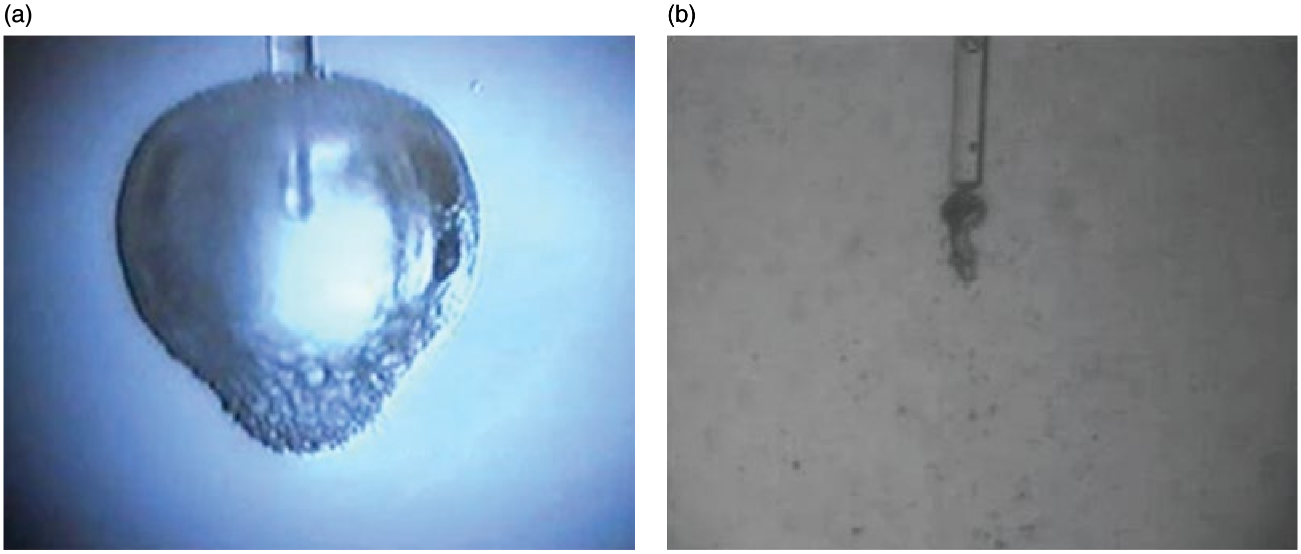

**Figure 144.2** (a) A large steam bubble forms at the end of a 550 μm laser fiber when using a Ho:YAG laser. (b) A small, relatively constant steam bubble forms at the end of a 550 μm laser fiber when using a Tm:YAG laser.

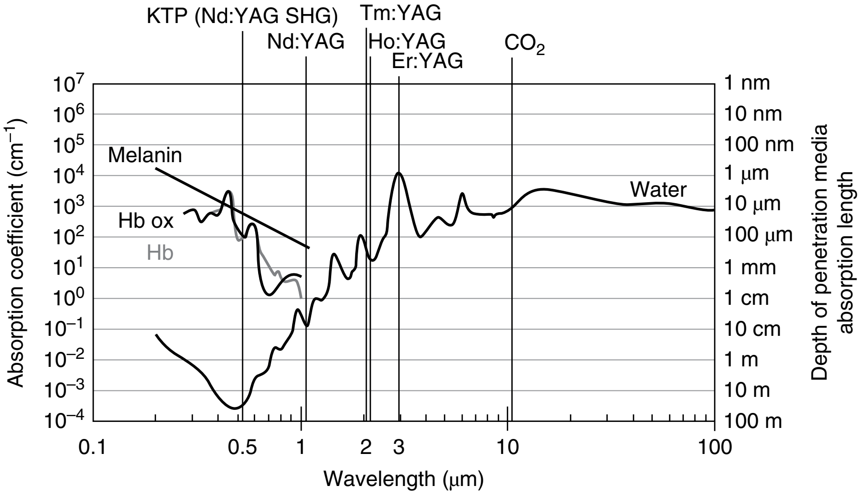

**Figure 144.3** Absorption spectra of prevailing body chromophores and wavelengths of different lasers. *Source:* Teichmann HO, Herrmann TR, Bach T. Technical aspects of lasers in urology. *World J Urol* 2007;25:221–225. Reproduced with permission of Elsevier.

For surgical applications, the most important process in the interaction of light and tissue is absorption [6]. When the laser beam hits tissue, a certain percentage is reflected by the boundary layer. This reflected radiation not only is lost for its surgical purpose but also becomes, in the form of heat, a potential risk to surrounding tissue. Reflection depends on the optical properties of the tissue and the irrigant surrounding it, but is not very dependent on wavelength and therefore may be neglected when evaluating a laser wavelength for surgical purposes. Since tissue is not homogeneous, part of the incident laser beam is scattered, taking the applied laser beam out of its intended direction. The degree of scattering depends on the size of the particles that the laser beam encounters and on the wavelength of the laser. Shorter wavelengths are scattered to a much higher degree than longer wavelengths. Blue laser radiation is scattered more than green, green more than red, and red more than infrared. This scattered fraction of laser energy is not only lost for the intended purpose but may also cause unintended side-effects [6, 8].

In order to achieve absorption, a chromophore is required. Useful body chromophores for surgical procedures are melanin, blood, and water, although melanin has no use in urologic applications [4–7, 12]. The wavelength dependencies of their absorption lengths are shown in Figure 144.3. The absorption length defines the optical pathway along which 63% of the incident laser energy is absorbed. Another concept, the extinction length, defines the depth at which 90% of the incident laser beam will have been absorbed and converted into heat [6].

A knowledge of the absorption process makes it easier to understand the laser–tissue interaction, both intended and unintended. When entering into an absorbing medium, the intensity of any laser beam decreases exponentially (Lambert–Beer's law). Absorbed laser energy is converted into heat and causes an increase in temperature. Depending on the density of absorbed heat, the impact on the tissue may vary between coagulation and vaporization. The temperature in tissue increases with the density of heat per volume of tissue. This offers the opportunity for various surgical procedures, such as vaporization, vaporesection (in continuous lasers), or vapoenucleation when used for the treatment of benign prostatic hyperplasia (BPH) [4, 6].

The tissue effect is determined by the power density of the absorbed laser power. The more complete the absorption by a tissue, the lower the absorbed laser power available to generate heat in the deeper layers. An understanding of this principle is important for any surgical laser application. At the same power level, a wavelength with a long absorption length may create a deep necrosis due to more laser power being available to be absorbed at the deeper levels, whereas with a laser wavelength with a much shorter absorption length, the absorbed laser power will be confined to a smaller volume. Effective delivery of high power to a small volume can lead to an effective increase of temperature above boiling point and to immediate confined vaporization of tissue [4, 6, 8].

## Lasers used for treatment of BPH

### Holmium lasers

Holmium lasers have been available for clinical use since the 1980s and multiple surgical transurethral laser prostatectomy techniques have been introduced.

#### Active (laser) medium

The YAG crystal is the material of choice for a variety of solid-state laser materials. As described earlier, a percentage of the $Y^{3+}$ ions at the crystallographic C-position (doping) are replaced with three valent rare earth ions, such as $Nd^{3+}$, $Ho^{3+}$, $Tm^{3+}$, or $Er^{3+}$, creating optically active solid-state laser materials. Under excitation, these crystals have the ability to amplify their own fluorescence light by stimulated emission of radiation [4, 13].

#### Excitation source

A flashlamp is the source of photons required for excitation of the laser medium emitting holmium laser radiation.

#### Wavelength

The holmium laser wavelength (2123 nm, nonvisible/infrared) is absorbed by water. The depth of penetration is 0.4 mm [4, 6].

#### Mode of operation

Energy is released in a pulsed mode [4].

#### Tissue chromophore and clinical translation of laser–prostate interaction

Holmium laser radiation is primarily absorbed by water as the main active chromophore. Energy absorption by the irrigant forms a steam bubble around the laser fiber tip and this result in a microexplosion, causing a jackhammer effect that can cut tissues. Due to the wavelength and the short high-peak power laser pulses, high-energy concentration can be achieved with each pulse, resulting in vigorous expanding and collapsing steam bubbles within the duration of the laser pulse [8].

These steam bubbles are used for surgical effects, such as coagulation and ablation. Coagulation occurs if the tissue is heated to temperatures greater than 70°C but less than 100°C and, either through decreasing the energy pulse or by pulling the fiber tip away from the tissue (defocused beam), the tissue temperature is lowered and ablation does not occur. Because the heat is absorbed into the tissue coagulation occurs. For ablation or cutting, the energy is absorbed by water in the prostate cells and the tissue is heated to more than 100°C.

Based on its physical properties, the holmium laser deemed versatile for different techniques of transurethral BPH treatment, such as holmium laser transurethral incision of the prostate (HoL-TUIP), holmium laser ablation of the prostate (HoLAP), holmium laser resection of the prostate (HoLRP), and holmium laser enucleation of the prostate (HoLEP) [4].

#### Laser fibers and evolution of holmium laser generators

More than one holmium laser generator has been developed for the treatment of BPH. Different levels of power range from 50 to 120 W. In the early days the tendency was to use high power for prostate ablation, starting from 60 to 80 and finally 100 W. Recently, the newly launched 120 W with its renovated XPEEDA fiber was introduced for prostate ablation. Higher power holmium lasers have also been used (80–100 W) for prostate enucleation, but Rassweiler et al., reported in 2008 on the feasibility of using low power for safe and effective HoLEP. They used a 40 W holmium laser machine to accomplish the enucleation procedure with reasonable efficacy [14]. Nevertheless, there are no randomized trials available to date assessing safety, efficacy, and cost saving associated with low-power HoLEP versus high-power HoLEP.

Laser generators are available from different manufacturers and the following fibers are available as laser delivery systems:

- End-firing fibers (single-use/reusable): larger fiber diameters have been used for prostate treatment (550–1000 µm).
- Side-firing fibers (single-use): DuoTome™ SideLite is a single-use, 550 µm fiber designed for a fluid environment that directs laser beam at 70°, useful for HoLAP. The maximum power output is 100 W and 4 J. Xpeeda™ D/S/L fiber is a single-use side-firing fiber that can deliver more energy to the tissue while in direct contact with it as proposed by the manufacturer for use with 120 W laser system [15].

## Thulium lasers

There are two different kinds of thulium lasers available: Tm:YAG (wavelength 2013 nm) lasers and Tm-fiber lasers (wavelength 1940 nm), which matches the water absorption peak in tissue at $\lambda = 1.94\,\mu m$ [16] (Figure 144.4).

### Active (laser) medium

The Tm:YAG is the optically active solid-state laser material. In contrast to the Tm:YAG laser, the active gain medium of the Tm-fiber laser is an optical fiber doped with thulium ions. A fiber laser utilizes the fiber itself as the amplification medium, and is pumped by a diode laser [7].

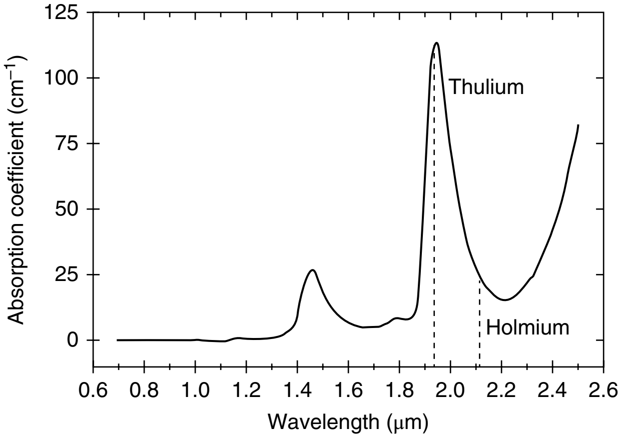

**Figure 144.4** Mid-infrared water absorption curve near 1.94 µm peak. Absorption coefficient for water is 114 $cm^{-1}$ at thulium wavelength of 1.94 µm and 36 $cm^{-1}$ at holmium wavelength of 2.12 µm. *Source:* Fried NM and Murray KE. High-power thulium fiber laser ablation of urinary tissues at 1.94 microm. *J Endourol* 2005;19:25–31. Reproduced with permission of Mary Anne Liebert, Inc.

### Excitation source

In contrast to the flashlamp excitation of the holmium laser, thulium ions are directly excited by high-power laser diodes. The narrow band excitation by laser diodes avoids excessive heat generation inside the crystal (or the fiber) as in the case of broadband excitation of the chromium ion by flashlamps in the holmium:YAG laser. This technical improvement increases the power efficiency of the laser by a factor of about 5 and eliminates the need for special electrical installation [4, 6, 16].

### Wavelength

The thulium laser wavelength (1940 nm (Tm-fiber laser), 2013 nm (Tm:YAG laser), nonvisible/infrared) is absorbed by water as the chromophore. The depth of penetration is 0.2 mm (Figure 144.2) [6, 12].

### Mode of operation

The Tm:YAG/thulium fiber laser is diode pumped, which allows it to be operated in either cw mode for applications requiring maximum hemostasis and coagulation, or in pulsed mode for applications requiring precision cutting [4, 16].

### Tissue chromophore and clinical translation of laser–prostate interaction

Thulium lasers operate at a wavelength close to the peak absorption of water, therefore using water as the chromophore. Although the absorption characteristics in tissue are similar to those of the holmium laser, the properties of the cw output in soft tissue surgery is superior. Because of the slightly shorter wavelength, the depth of penetration is decreased to 0.25 mm. Instead of the tearing action on tissue which is caused by the pulsed operation of the holmium laser, the cw output allows smooth incision and vaporization of tissue with excellent hemostasis due to a relatively constant steam bubble between the fiber tip and tissue, compared with the expanding steam bubble of the holmium laser (Figure 144.2a,b) [4].

A major technical advantage arises out of the temperature stability of the water molecule, which is the target body chromophore for the 2 µm wavelength. Water retains its absorption properties when heated by the laser beam up to its boiling point, which is the onset of tissue vaporization. The tissue left behind after each laser pass is covered by a coagulated seam of tissue which provides hemostasis. It still contains sufficient water for efficient absorption of the following laser pass. Thus the laser tissue effect remains unchanged and effective throughout the entire surgical procedure [6].

Because of the high proportion of vaporization during thulium laser treatment of the prostate, four different techniques have been defined: Tm:YAG vaporization of the prostate (ThuVaP), Tm:YAG vaporesection of the prostate (ThuVaRP) Tm:YAG vapoenucleation of the prostate (ThuVEP), and Tm:YAG laser enucleation of the prostate, a transurethral blunt enucleation of the prostate with Tm:YAG laser-assist [17].

#### Laser fibers and evolution of thulium laser generators

Thulium laser generators have been produced with wavelengths of 1940 nm (Tm-fiber laser), 2010 nm (Tm:YAG laser), and 2013 nm (Tm:YAG laser) and different levels of power, ranging between 50 and 200 W. High-powered thulium lasers (120–200 W) have mainly been used for ThuVAP or ThuVaRP, while 70–90 W thulium lasers are sufficient for ThuVEP or ThuLEP. Laser generators are available by different manufacturers and the following fibers are available as laser delivery systems:

- End-firing fibers (single-use/reusable): larger fiber diameters have been used for prostate treatment (optical core: 550–1000 μm).
- Side-firing fibers (single-use): SideFib™ is a single-use, optical core, 600 μm fiber with side-fire deflection of 78°, which is useful for ThuVAP.

### High-power 532 wavelength laser (characterized by its green light color)

Four generations of 532 wavelength or “GreenLight” lasers have been made: the 60 W KTP laser, the 80 W KTP laser, the 120 W lithium triborate (LBO) HPS laser, and the 180 W LBO XPS laser (all wavelength 532 nm) [18].

#### Active (laser) medium

The KTP laser is a derivative of the Nd:YAG laser. The additional KTP crystal (frequency doubling crystal) in the laser resonator converts the fundamental Nd:YAG wavelength (1064 nm) by SHG into 532 nm radiation [6].

#### Excitation source

An arc lamp is the source of photons required for excitation of the Nd:YAG crystal in first-generation GreenLight lasers. In second-generation GreenLight lasers, the Nd:YAG laser is diode pumped.

#### Wavelength

The green light wavelength (532 nm) is strongly absorbed by hemoglobin [6]. The depth of penetration is 0.8 mm in prostate tissue [4]. The 532 nm wavelength laser operates at a wavelength where the absorption in water is at a minimum (Figure 144.3). Without the presence of the hemoglobin molecule the extinction length for the KTP laser increases dramatically and the beam transmits through the irrigant with minimal power loss until it reaches its main tissue target, with effective penetration into tissue containing the active main chromophore for power absorption. Although absorption of light energy is shallow, it is deeper than the superficial effects of a holmium and thulium procedure, and can remove tissue via a true tissue vaporization effect. The challenge with this technique is to limit the heat effects to the target tissue. For effective volume reduction vaporization and minimal tissue coagulation effect, local thermal conduction is needed from the area of primary vaporization [6].

#### Mode of operation

Energy is delivered in a cw or quasi-cw mode [6, 18].

#### Tissue chromophore and clinical translation of laser–prostate interaction

The high-power 532 nm or KTP/LBO wavelength penetrates vascular tissue only a few micrometers (0.8 mm). In red, well-perfused tissue the density of absorbed power is high and results in an immediate increase of tissue temperature above the boiling point. Heat then diffuses deeper into the tissue layers via continuous irradiation at a single point. The longer the area is heated the deeper the effect. This phenomenon does not produce enough energy for vaporization, but results in coagulation due to local convection thermal energy that is high enough to denature protein. The unique characteristic of the 532 nm wavelength with melanin and hemoglobin as the active selective chromophores as well as its nonabsorption in an aqueous medium lead to the technique being given the name “photoselective vaporization of the prostate” (PVP) [18, 19].

The PVP technique results in a large amount of tissue being vaporized with a coagulated seam that provides hemostasis. This coagulated seam is produced by the local increase in temperature that is not enough for vaporization but enough for coagulation. Although subsequent laser passes travel through the coagulated seam, increasing the laser beam scattering, the effective use of high power and quick passes can limit the effects of scattering. Although lack of absorption in coagulated tissue can impair efficient removal because of the scattering of the green wavelength, this effect is easily overcome by the applications of higher power and power density as conferred with the more powerful 180 W 532 nm laser systems or GreenLight XPS laser system [6].

Side-firing fibers are used exclusively for PVP to ensure better visual control on the point of impact of the laser beam on the prostatic lobes [6].

### Laser fibers and the evolution of KTP laser generators

Four generations of GreenLight lasers with 60, 80, 120, and 180 W power have been produced. The 60 W KTP was a very effective and safe laser, but its lower power resulted in a less-than-ideal vaporization effect and speed with higher levels of coagulation necrosis effects. The 80 W was therefore created in order to increase vaporization speed. The 120 W system has the same properties as the 80 W laser but uses a different SHG crystal [20]. A LBO crystal is used and a Nd:YAG laser beam is passed through this medium in order to create the 532 nm wavelength. This LBO system is better collimated in comparison to the KTP beam.

The 180 W laser utilizes a control power feedback mechanism that exits the system and has a high-power fiber. The fiber has a thicker inner core (MoXy Fiber, American Medical Systems, San Jose, CA, USA) [18, 21]. Further modifications made were to the coagulation power mode. This coagulation mode is delivered across a variety of intermittent pulses [21], which copy that of the power in electrocautery coagulation used for hemostasis. This fiber has been adapted to be used with arterial bleeders. In addition, intermittent pulses and continuous flow of room temperature irrigant over the tip of fiber help to limit the laser coagulation heat on the contact tissue [21]. The overall power of the 180 W system improved the rate of vaporization efficiency [21]. In order to have maximum output of 180 W, a new fiber was necessary. This new fiber has a wider diameter (750 µm vs. 600 µm), which provides a wider and more efficient zone for vaporization. This increases the beam area by 50% [18].

The following side-firing single-use fibers are available as laser delivery systems:

- 1.75 mm OD, 600 µm CCD, 70° deflecting, silica fiber ADD Stat™ delivery device but by an 88% more collimated beam and smaller spot size, resulting in much higher irradiance or power density in W/cm$^2$ than its two predecessors with a beam divergence of 8° vs. 15° [18, 22] (120 W LBO PVP).
- 2.10 mm OD, thicker 750 µm CCD, continuously cleaned/cooled, metal-capped, silica, MoXy™ fiber. This has the same 8° beam divergence but due to its larger 750 µm CCD the new fiber emits a larger diameter laser beam. Consequently, it creates a 50% larger spot size. However, since it also emits 50% more power, it achieves the same irradiance or power density in W/cm$^2$ as the existing ADD Stat™ fiber (50% less power and 50% smaller spot size) [18] (180 W LBO PVP).

### Others

**Diode lasers**

There is no unique diode laser. The term diode laser defines a group of lasers using a semiconductor excited by an electrical current as the excitation source to generate laser radiation. By using different semiconductor elements (GaAlAs (750–870 nm), InGaAs (900–1000 nm), InGaAsP (1300–1550 nm)) and layer structures, the generation of various wavelengths is possible (Figure 144.3), providing laser systems emitting at 940, 980, 1318, and 1470 nm [5]. Reviewing the basics of laser–tissue interaction and Figure 144.3, it becomes clear that different wavelengths must be judged independently [5]. The target chromophore differs depending on wavelength. Compared with the GreenLight LBO laser, different diode laser systems showed comparable or superior tissue ablation rates and lower bleeding rates. However, tissue necrosis and penetration depth were significantly higher [23–25].

## Dedication

This chapter is dedicated to Professor Mostafa Elhilali (1937–2017) who passed away on April 29, 2017. Professor Elhilali made a huge scientific contribution to different areas of urology. Specializing in endourology, he was involved in developing and establishing the holmium laser enucleation of the prostate technique for the treatment of benign prostatic obstruction.

## Introduction

Transurethral resection of the prostate (TURP) has been the reference standard for the treatment of benign prostatic hyperplasia (BPH) for decades. It was reported that TURP was associated with significant perioperative morbidity (13–24%) [1], but with significant technical advancements over years its perioperative morbidity has been significantly reduced (11.1%) [2]. However, it still has limitations that increase the perioperative morbidity, particularly when treating large prostates and patients with coagulopathy. Reich et al. showed that with resected prostate weight more than 60 g, blood transfusion rate was 9.5%, transurethral resection syndrome was 3%, surgical revision rate was 9.8%, and perioperative mortality was 0.71% [2]. Furthermore, data showed that coagulopathy independently impacted TURP outcome in terms of more bleeding complications [3].

Laser prostatectomy was introduced as a less invasive modality for treatment of BPH, because it overcomes the disadvantages and limitations of the standard TURP and open prostatectomy. It is much less invasive than the open procedure [4], and, because it uses physiological saline as an irrigant, the incidence of transurethral resection syndrome is reduced and a higher safety profile is achieved in patients with comorbidity who are on anticoagulants or antiplatelets during surgery [5]. Laser prostatectomy also can be used to tackle large prostate glands beyond the limits of TURP. It is often done as day surgery with a shortened catheterization time. These considerations result in it being more cost effective [6].

## History and evolution

The holmium (Ho) laser has been associated with strong clinical evidence for its effectiveness in many applications in urology, such as incision of ureteral stricture [7], lithotripsy of urinary calculi [8], ablating superficial urothelial tumors [9], bladder neck incision (BNI) [10], and surgical management of BPH.

The combination of the Nd:YAG laser with the Ho:YAG laser was used early on to vaporize and coagulate tissue using a technique known as combination endoscopic laser ablation of the prostate (CELAP). The initial experience of this technique was first reported by Gilling et al., who found the use of the Nd:YAG laser led to a longer catheterization time, delayed symptom improvement, and high recatheterization rate (26%) [11]. These side-effects limit the usefulness of this technique, and CELAP has been replaced by the holmium-only technique. Since its first use in 1994, various techniques using the holmium laser wavelength have been used in the surgical management of BPH: holmium laser ablation (HoLAP), resection (HoLRP), and enucleation of the prostate (HoLEP) [12].

## Physics

Every new laser technology has specific advantages; however, its physics may result in significantly different outcomes. The holmium:yttrium–aluminum–garnet (Ho:YAG) laser emits a pulsed, invisible infrared beam with a wavelength of 2140 nm, which is absorbed strongly by water (which constitutes 60–70% of the prostate).

The depth of penetration is 0.4 mm, which predominantly causes vaporization without a deep coagulation zone when used with a side-firing fiber. It provides a precise incision and enucleation while maintaining hemostasis when used with an end-firing fiber. Energy absorption by the irrigant forms a vapor bubble around the laser fiber tip and this result in a microexplosion, causing a jackhammer effect that can cut tissues or disintegrate stones when in close contact to the target tissue. If direct contact is not adequately maintained, laser efficiency will be reduced due to consumption of energy in the formation of vapor bubbles [12, 13].

## Equipment and instruments required for holmium laser management of BPH

- Laser capital equipment: High-power holmium laser system is essentially required for management of BPH. As low as 50 W laser power has been used for holmium laser-based transurethral prostate procedures, but 80–100 W systems are the most frequently used [14]. Recently a 120 W system has been introduced with significant enthusiasm, particularly for prostate vaporization.
- Endoscopy set: Continuous-flow 26 Fr resectoscope (inner, outer sheath, and an obturator system), 30° optical lens and laser guide probe (used for stabilization of laser fiber), working element (thumb controlled for the laser guide probe), and saline for irrigation (Figure 145.1).
- Video monitoring system.

## Holmium laser transurethral incision of the prostate

### Technique (see Video 145.1)

Holmium laser transurethral incision of the prostate (HoL-TUIP) is performed using a 100 W Ho:YAG laser and a 550 μm end-firing fiber. The bladder neck is deeply incised at 5 and/or 7 o'clock, just distal to each ureteral orifice, using laser energy to create a trough down to the true capsule to either side of the verumontanum (laser energy of 2 kJ and rate of 50 Hz). Usually a single incision is sufficient as the bladder neck splits open wide. Rarely a second incision is necessary on the other side. A two-way 22 Fr Foley catheter is inserted and connected to straight drainage [10] to be removed before discharge the same day if the urine is clear.

### Safety

HoL-TUIP can be performed safely as a catheter-free outpatient procedure [15].

### Efficacy

Cornford et al. confirmed the efficacy of this technique at 2-year follow-up. The mean maximum urinary flow rate ($Q_{\text{max}}$) increased from 9.7 to 18.2 ml/s [15].

### Durability

The long-term outcome could be improved and the reoperation rate minimized with appropriate selection of cases. Elkoushy et al. reported on 82 patients who underwent HoL-TUIP; 9 (11%) patients were reoperated for recurrent symptoms of bladder outlet obstruction. Only prostate size independently predicted reoperation after HoL-TUIP (adjusted odds ratio [aOR] 7.12, 95% confidence interval [CI] 2.92–9.14, $P = 0.01$) with cut-off value of prostate volume of 29 ml to characterize long-term reoperation, with area under the curve (AUC) of 0.96, sensitivity of 89.7, and specificity of 88.9 [16].

### Cost efficacy

Comparing cost efficacy for HoL-TUIP and GreenLight (532 nm) laser photoselective vaporization of the prostate (PVP) for treatment of small prostates including high-risk patients, the mean estimated cost per HoL-TUIP procedure was significantly lower than that per PVP procedure. The higher cost of PVP was mainly due to the cost of a single-use laser fiber and a significant difference in hospital admission time [10].

## Holmium laser ablation of the prostate

### Technique

Using a 550 μm side-firing laser fiber with laser settings ranging from 2 J and 50 Hz to 3.2 J and 30 Hz, without the need for any tissue retrieval instruments. HoLAP is performed with the patient under general or regional anesthesia and normal saline is used as the irrigant. Vaporization of the prostate usually starts at the bladder neck using the side-firing laser fiber to make a bladder neck incision at 5 and 7 o'clock; then the laser fiber is gently moved over the surface of the obstructed lobe toward the apex of the prostate proximal to the verumontanum. The end-point of the laser procedure is a TURP-like cavity lined by capsular fibers [17].

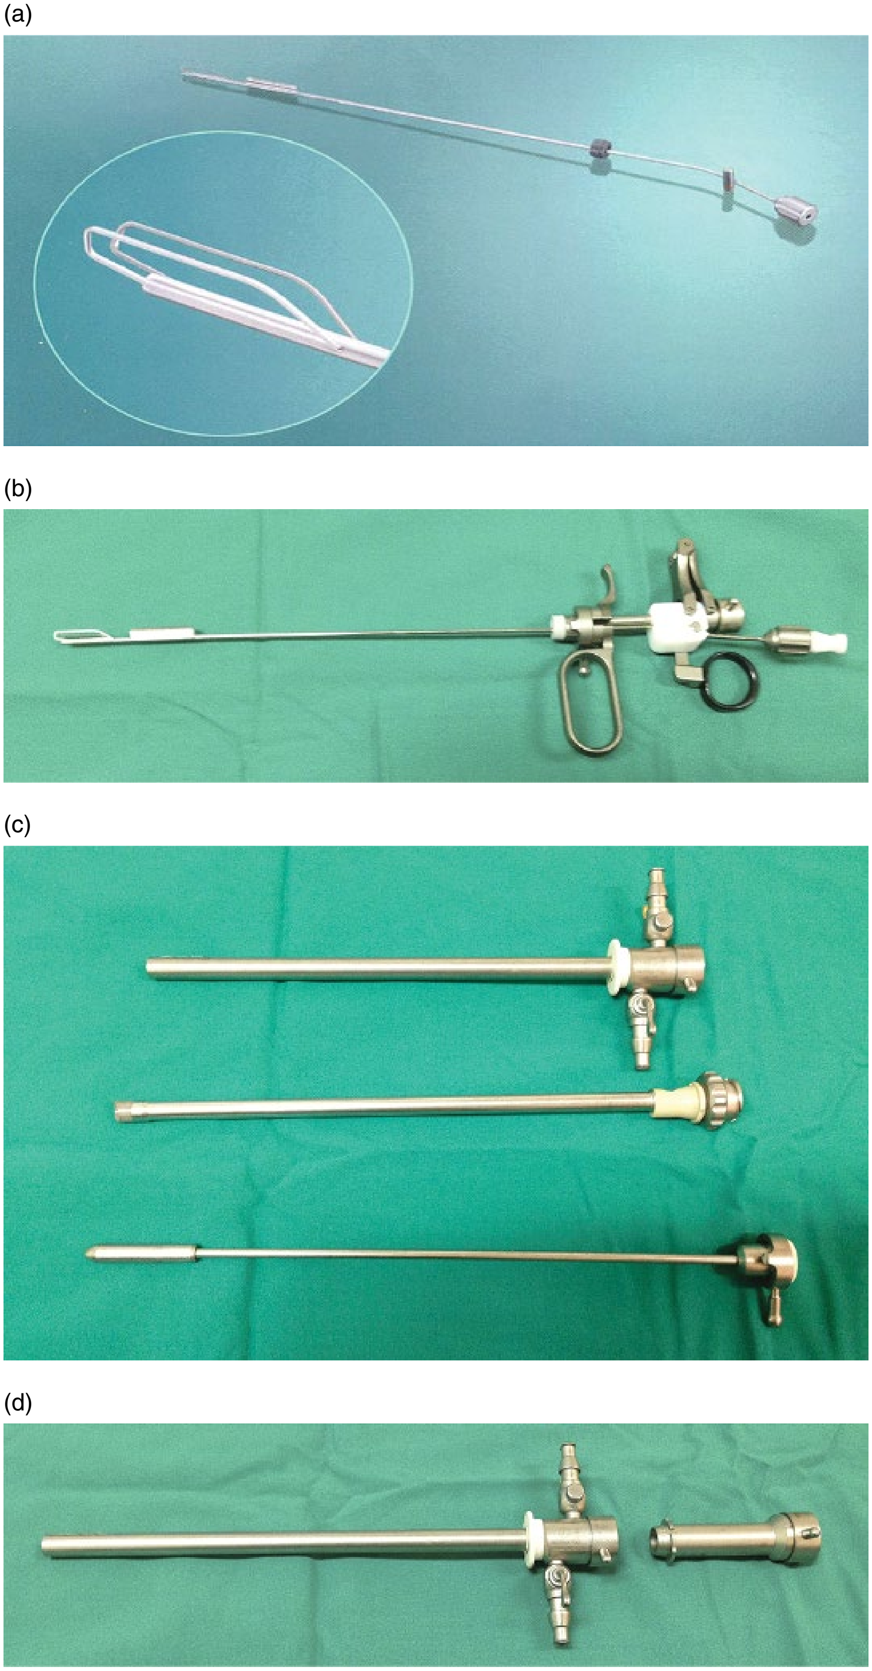

**Figure 145.1** Endoscopy set. (a) Laser guide probe with retracting beaks. (b) Laser guide probe with retracting beaks. (c) Continuous flow 26 Fr resectoscope with inner and outer sheaths and an obturator system. (d) Connecting piece/adaptor for the outer sheath to fit indirect nephroscope for morcellation.

### Safety

A controversial issue related to HoLAP when compared to TURP is the lack of tissue for histopathologic examination, which could lead to diagnoses of prostatic carcinoma being missed. Therefore, it is mandatory to perform a thorough evaluation of patients with an elevated prostate specific antigen (PSA) level or abnormal digital rectal examination (DRE), with transrectal ultrasound (TRUS)-guided biopsies prior to the intervention. Recently, with the increased popularity of using multiparametric MRI we can probably reduce the chance of missing significant cancer. It is also mandatory to continue postoperative PSA and DRE surveillance.

### Efficacy

In a randomized trial comparing HoLAP and TURP in men with prostates smaller than 60 ml, the subjective and objective improvements in both groups were similar at 1 year follow-up. However, the advantages of HoLAP over TURP included less dysuria and bleeding, and shorter hospital stay and catheter time, without need for any postoperative irrigation [17].

### Durability

Elshal et al. reported after a median of 71.3 months in a randomized trial comparing HoLAP versus GreenLight (532 nm) laser PVP. Retreatment for recurrent infravesical obstruction was 19.2% in HoLAP and 25% in PVP ($P > 0.05$). Smaller prostate volume was significantly associated with bladder neck contracture (BNC) after laser ablation, regardless of the type of laser used. BNC and *de novo* urethral stricture seem to be the main causes for an early (first-year) reintervention. Redo treatment for recurring prostate adenoma was associated with less postoperative PSA reduction (less than 20%) suggesting inadequate tissue ablation. At 7 years follow-up of 34 patients who underwent HoLAP, there was an 83% improvement in $Q_{\max}$, a 47% decrease in symptom score, reoperation rate of 15%, and recatheterization rate of 9% [18, 19].

### Cost efficacy

Looking for cost efficacy of both HoLAP and GreenLight (532 nm) laser PVP for treatment of small to moderate size prostate (less than 60 ml), accounting for all clinic visits and readmissions for reoperations, total costs were 200.45 Canadian dollars lower in the HoLAP group [19].

### Future perspectives

Xpeeda™ D/S/L fiber is a single-use, side-firing fiber that can deliver more energy to the tissue while in direct contact with it, as proposed by the manufacturer for use with 120 W laser system. Laser ablation with the new fiber might revive the use of holmium laser in prostate ablation for further clinical studies [20].

## Holmium laser resection of the prostate

### Technique

Before the development of the morcellator for tissue retrieval, Gilling et al. developed a technique that aimed to resect prostatic tissue by the holmium laser, similar to TURP. The resected pieces were small enough to be retrieved by a modified resectoscope loop or Ellik evacuator. HoLRP starts with bilateral incision to define the depth and amount of tissue to be removed. The next step is to join the two incisions just in front of the verumontanum to undermine the median lobe and deposit it into the bladder. Incisions at 1 and 11 o'clock position over the entire length of the prostate are needed to define the upper margin of the excision of the lateral lobes. Dissection occurs precisely in the plane between the adenoma and capsule in a retrograde fashion until only a bridge of tissue remains at the bladder neck [21]. The technique of HoLRP produces a cavity identical in appearance to TURP, but with a relatively bloodless procedure that results in a short catheter time, immediate functional improvement, and minimal postoperative irritative symptoms.

### Safety

HoLRP offers significant improvements over TURP in terms of catheterization time, length of hospital stay, risk of bleeding, and incidence of untoward events [22].

### Efficacy

Fraundorfer et al. reported in their randomized trial comparing HoLRP to TURP that HoLRP offers equivalent outcomes to TURP in terms of rapid relief of symptoms and improved urodynamic parameters [22].

### Durability

The long-term data have shown sustained improvement of flow rate and symptom score for a minimum of 4 years [23].

### Cost efficacy

HoLRP offers a 24.5% cost savings over TURP when in-hospital and postdischarge events were analyzed.

Furthermore, 93 procedures annually for 5 years would achieve total machine payback, including fiber and service costs [22].

## Holmium laser enucleation of the prostate

HoLEP reproduces the removal of the obstructing prostatic tissue with a true anatomic surgical enucleation of the adenoma, identical to using the index finger in open prostatectomy. The advantages of this technique include an almost bloodless field, allowing better vision with simultaneous coagulation of all bleeding vessels. Moreover, the dissection can be sharp or blunt. Three-dimensional awareness and hand–eye coordination are mandatory in this technique. The visibility in HoLEP, compared with standard TURP, is much better because of the bloodless field and the greater image magnification.

### Technique

#### Inspection

Inspection of the prostate anatomy looking for presence or absence of grossly enlarged median lobe and the depth of the grooves at the bladder neck determines the location of the first incision and plan of enucleation.

#### Enucleation

- Three-lobes technique is used for grossly enlarged median lobe and deep grooves at the bladder neck (see Video 145.2.a)
- Two-lobes technique is used whenever there is only a single or no deep groove at the 5 or 7 o'clock positions of the bladder neck (as in the majority of cases).
- In one-lobe technique (en-bloc technique) the whole adenoma is dissected as one unit for delivery into the bladder [24].

Following median lobe enucleation (in case of three-lobes technique) or creation of the initial incision at the deepest groove at the bladder neck (in case of two-lobes technique) (see Video 145.2.b.i), lateral lobe enucleation is achieved.

Enucleation is done using a combination of blunt and sharp dissection in a retrograde fashion. The blunt enucleation is achieved by using the tip of the scope, just like using a finger, to separate the adenoma from the surgical capsule in a technique similar to traditional retropubic prostatectomy but in a retrograde manner.

The operator should always use a rotating movement to follow the contour of the prostate and care must be taken to avoid using excessive force so as not to unnecessarily stretch the external urinary sphincter or go through the surgical capsule. Blunt enucleation should be avoided if the tissues do not separate easily. Instead, the laser should be used to cut any attachments. The proper plane can be identified from its appearance, as well as from the ease with which the tissues separate (see Video 145.2.b.ii). The dissection of the adenoma continues, progressing toward the bladder neck. When the adenoma is separated laterally and the anterior aspect of the prostate is reached, the dissection is extended across the midline in order to facilitate the later separation of the two lobes in the midline anteriorly when the 12 o'clock incision is performed, eliminating any guesswork about the depth needed.

Eventually, the adenoma is attached at the bladder neck, apical mucosal strip at the level of the urinary sphincter, and the anterior commissure to the contralateral adenoma.

The adenoma is sharply dissected from the bladder neck completely then the apical mucosal strip is carefully incised using short energy bursts at settings of 1.5 J at 30 Hz for an energy level of 45 W, to minimize the risk of thermal damage to the sphincter (see Video 145.2.b.iii). The incision is extended through the anterior commissure, separating the two adenomas without the need for guesswork on the depth of incision. The lateral lobes are gently pushed into the bladder.

#### Hemostasis

Special emphasis is placed on achieving excellent hemostasis before starting morcellation because the visibility with the indirect nephroscope is not as good as with the cystoscopic lens. When coagulating a bleeding vessel, the laser fiber is defocused but directed end-on toward the bleeding point. A whitening of the tissue around the vessel can often be used as an indicator of adequate coagulation (see Video 145.2.c).

#### Morcellation

There are two popular commercially available tissue morcellators. The main differences between them are the type of movement of the cutting blades (guillotine vs. oscillation) and shape of the blade (nontoothed vs. toothed) in the VersaCut™ (Lumenis Inc., San Jose, CA, USA) and Piranha (Richard Wolf GmbH, Knittlingen, Germany) morcellators [25], respectively (see Video 145.2.d). Alternatives to tissue morcellators are the mushroom technique and mini-laparotomy suprapubic extraction of the enucleated adenoma [26].

Morcellator is introduced through a long nephroscope and an adaptor is used to fit the nephroscope with outer sheath of the 26 Fr resectoscope.

Morcellation is one of the most critical steps of the procedure and is often considered potentially dangerous. In order to avoid complications, two principles need to be strictly observed. First, the patient's bladder should be adequately distended. This is achieved by ensuring that the patient's abdominal muscles are relaxed and that the irrigation inflow is not interrupted, a second inflow tubing attached to the exit tap adds more security and ensures bladder fullness at all times. Second, the morcellation process should always be performed under direct vision. This is achieved by having adequate hemostasis and by keeping the engaged piece directly in front of the lens of the nephroscope, with the nephroscope tip and cutting blades in the middle of the bladder. Lastly the prostatic fossa is inspected for bleeders or any residual adenomas (see Video 145.2.e).

## Postoperative care

At the end of the procedure, a 20–22 Fr, 30 ml balloon two-way Foley catheter is inserted. Sometimes a stylet is needed to insert the catheter. The catheter is fixed to a Y-connector, which is used to deliver intermittent irrigation to the bladder if needed in the recovery room. Rarely, a three-way catheter and continuous bladder irrigation are used.

The catheter is removed on the next morning unless otherwise indicated and the patient is discharged.

## Safety

### Perioperative

Naspro et al. performed a randomized study comparing HoLEP to open prostatectomy in 80 patients (41 vs. 39 patients, respectively) with a prostate size greater than 70 g [26]. HoLEP was shown to be safer than open prostatectomy in the perioperative period, requiring a lower number of blood transfusions (4% vs. 12.8% $P < 0.001$) in addition to a shorter catheterization time (1.5 vs. 4.1 days, $P < 0.001$) and hospital stay (2.7 vs. 5.4 days, $P < 0.001$) [27]. Furthermore, the safety in elderly people (octogenarians) with high morbidity index [5] and in patients who are on an ongoing anticoagulation/antiplatelet therapy during the procedure have been reported [28].

## Continence

Postoperative transient stress urinary incontinence (SUI) following HoLEP has been reported. Elmansy et al. found that risk of postoperative SUI is associated with prostate volume more than 81 g, postoperative reduction in PSA more than 84%, and in patients with diabetes mellitus [29]. Some reports showed high incidence of postoperative SUI in the first year that significantly improved with time and pelvic floor exercise [30]. Postoperative transient urge urinary incontinence (UUI) is a time-limited event that is related to the time needed for detrusor muscle recovery with or without anticholinergic medications.

Early postoperative SUI occurs as a rare event after HoLEP and is reported in around 2% of cases, which is comparable with results from TURP and open prostatectomy [31, 32].

## Urinary retention

Patients with urinary retention represent a particular challenge to urologists, as they often experience inferior functional outcomes and a higher complication rate when compared to patients without urinary retention. Peterson et al. retrospectively evaluated 164 patients in urinary retention treated by HoLEP [33]. Mean duration of urinary retention was 28.9 days (range 2–365 days). Their results confirmed the safety and reliability of this procedure for treating urinary retention in men with large prostates. All patients were able to void following treatment and remained catheter free. Mean urine flow rate was 26.7 ml/s (range 4.3–54.8 ml/s) and mean postvoid residual (PVR) was 32.5 ml (range 0–150 ml).

The outcome for patients with chronic urinary retention and hypotonic bladder may be less satisfactory. Mitchell et al. reported on 14 patients with detrusor hypocontractility and 19 patients with acontractility and evidence of benign prostatic obstruction (BPO) who underwent HoLEP. Preoperatively, 5 (35.7%) men with hypocontractility and 19 (100%) men with acontractility had catheter-dependent urinary retention for a median of 3 and 9 months, respectively. At a median follow-up of 24.7 months, all 5 (100%) men with hypocontractility and 18 of 19 (94.7%) men with acontractility were voiding spontaneously without the need for intermittent catheterization. Individuals with hypocontratile bladders had statistically significant improvements in the American Urological Association Symptom Index (AUA-SI) (21.5 vs. 3; $P = 0.014$), maximum urine flow ($Q_{\max}$ 10 vs. 21 ml/s; $P = 0.001$), and PVR (250 vs. 53 ml; $P = 0.007$) from baseline to postoperative assessments. In patients with an acontractile bladder, 15 of 19 (78.9%) displayed significant return of detrusor contractility, whereas 4 of 19 (21.1%) were voiding exclusively by Valsalva effort on follow-up urodynamic study. Postoperatively, patient satisfaction, as ascertained by AUA-SI, was high for both groups [34].

## Sexual function

HoLEP had no negative impact on sexual function. Furthermore, sexual satisfaction improved in proportion to the improvement in lower urinary tract symptoms following HoLEP [35]. In a study of 99 HoLEP patients, significant improvement in most of the subdomains of the International Index of Erectile Function (IIEF) was observed, although the orgasmic function domain did not show a significant substantial change, which may be related partially to the high prevalence of retrograde ejaculation/anejaculation [36]. This finding is consistent with what was reported after open enucleation procedure (suprapubic prostatectomy) of significant increase in sexual desire and overall satisfaction despite the high prevalence of retrograde ejaculation (80–90%) and minimal impact on erectile function.

## Efficacy

### Operative efficacy

In a study of matched pairs of open prostatectomy, TURP, and HoLEP, resection speed and operative time for laser enucleation were statistically significantly faster than for TURP (0.61 vs. 0.51 g/min and 62 vs. 73 minutes, $P < 0.01$) and similar to those of open prostatectomy (0.92 vs. 1.0 g/min and 101 vs. 90 minutes, respectively, $P \geq 0.21$). Based on resection speed, HoLEP is faster than TURP and similar to simple open prostatectomy [37].

### Urinary outcome measures

HoLEP produces immediate and sustained improvement of objective and subjective outcomes similar to both open prostatectomy and TURP. The pre- and postoperative urodynamic assessment has confirmed that the relief of obstruction with HoLEP is superior to, or at least equivalent to, TURP and open prostatectomy [38–40]. Wilson et al. compared the functional outcomes of HoLEP to TURP in a randomized study of patients with a prostate size of 40–200 g. At one-month follow-up, functional outcomes in terms of AUA-SI score (8.6 vs. 5.7) and $Q_{\max}$ (22.3 vs. 18.4 ml/s) were observed in the HoLEP and TURP groups, respectively [38]. The improvement in functional outcomes was maintained for up to 24 months.

In 2007, Ahyai et al. published interesting data regarding the efficacy of HoLEP compared to TURP [31]. A total of 200 patients with a prostate volume of less than 100 ml were prospectively randomized to HoLEP or TURP and followed up for up to 3 years. At 2- and 3-year follow-up, HoLEP micturition outcomes compared favorably with those of TURP. The AUA-SI score was significantly better at 2 years postoperatively in the HoLEP group (1.7 vs. 3.9, $P < 0.0001$) and similar at 3 years (2.7 vs. 3.3, $P = 0.17$). PVR was significantly better at 2 years (5.6 vs. 19.9 ml, $P < 0.001$) and 3 years (8.4 vs. 20.2 ml, $P = 0.012$) postoperatively in the HoLEP patients. However, $Q_{\max}$ was similar in the HoLEP and TURP groups at 2 years (28.0 vs. 29.1 ml/s, $P = 0.83$) and at 3 years (29.0 vs. 27.5 ml/s, $P = 0.41$) postoperatively.

In comparing HoLEP to open prostatectomy, Naspro et al. demonstrated equivalence in terms of improvement in obstruction, starting with the three months follow-up and reaching a plateau at the 24 months follow-up [27]. At 24 months, $Q_{\max}$ had improved to clinically normal levels in both the HoLEP and open prostatectomy groups (19.19 vs. 20.11 ml/s, $P < 0.9$, respectively).

Kuntz et al. confirmed the previously reported data on large prostates in a randomized trial in patients with prostates larger than 100 g [39]. Both HoLEP and open prostatectomy resulted in effective and long-lasting postoperative improvements in symptom scores, $Q_{\max}$, and PVR. The differences between HoLEP and open prostatectomy in functional outcomes were not significant at each time point during follow-up.

### Prostate specific antigen and prostate volume reduction

Measurement of PSA may be a useful surrogate tool for the objective assessment of the amount of residual prostatic tissue following different therapies for BPH. It has been reported that serum PSA level is markedly reduced after open prostatectomy or transurethral surgery, as the transition zone is the major source of PSA production. Stamey et al. reported the changes in PSA after open prostatectomy or transurethral procedures for the treatment of BPH [41]. There was a mean decrease in PSA of 95% in the open prostatectomy group and of 84% in the TURP group (73 men). Others have confirmed a mean percentage PSA reduction of 70–75% after TURP [42].

HoLEP produces a significant reduction in PSA that correlates well with the weight of adenoma resected (Figure 145.2). Tinmouth et al. examined PSA data before and after HoLEP from two institutions performing high volumes of this procedure in a retrospective evaluation of 509 patients [43]. The average weight of adenoma resected was 49.8 g (range 5–300 g) in the McGill group and 90.4 g (range 7.9–312 g) in the Methodist Hospital group, and the mean decrease in PSA 81.7% and 86%, respectively. Elmansy et al. evaluated 335 patients treated with HoLEP between 1998 and 2006 in a longitudinal study [44]. They found that the mean PSA dropped from 5.44 to 0.91 ng/ml and the mean PSA reduction was 75.4%, indicating that HoLEP is an effective technique in near complete adenoma resection. Moreover, this percentage reduction in PSA was maintained for up to 7 years follow-up, suggesting that the reduction in gland size after HoLEP is durable and more complete. In addition, they proposed that if the reduction of PSA after HoLEP is less than 50%, closer follow-up with PSA measurements every 3–6 months for the first 2–3 years is indicated to allow earlier detection of prostate cancer.

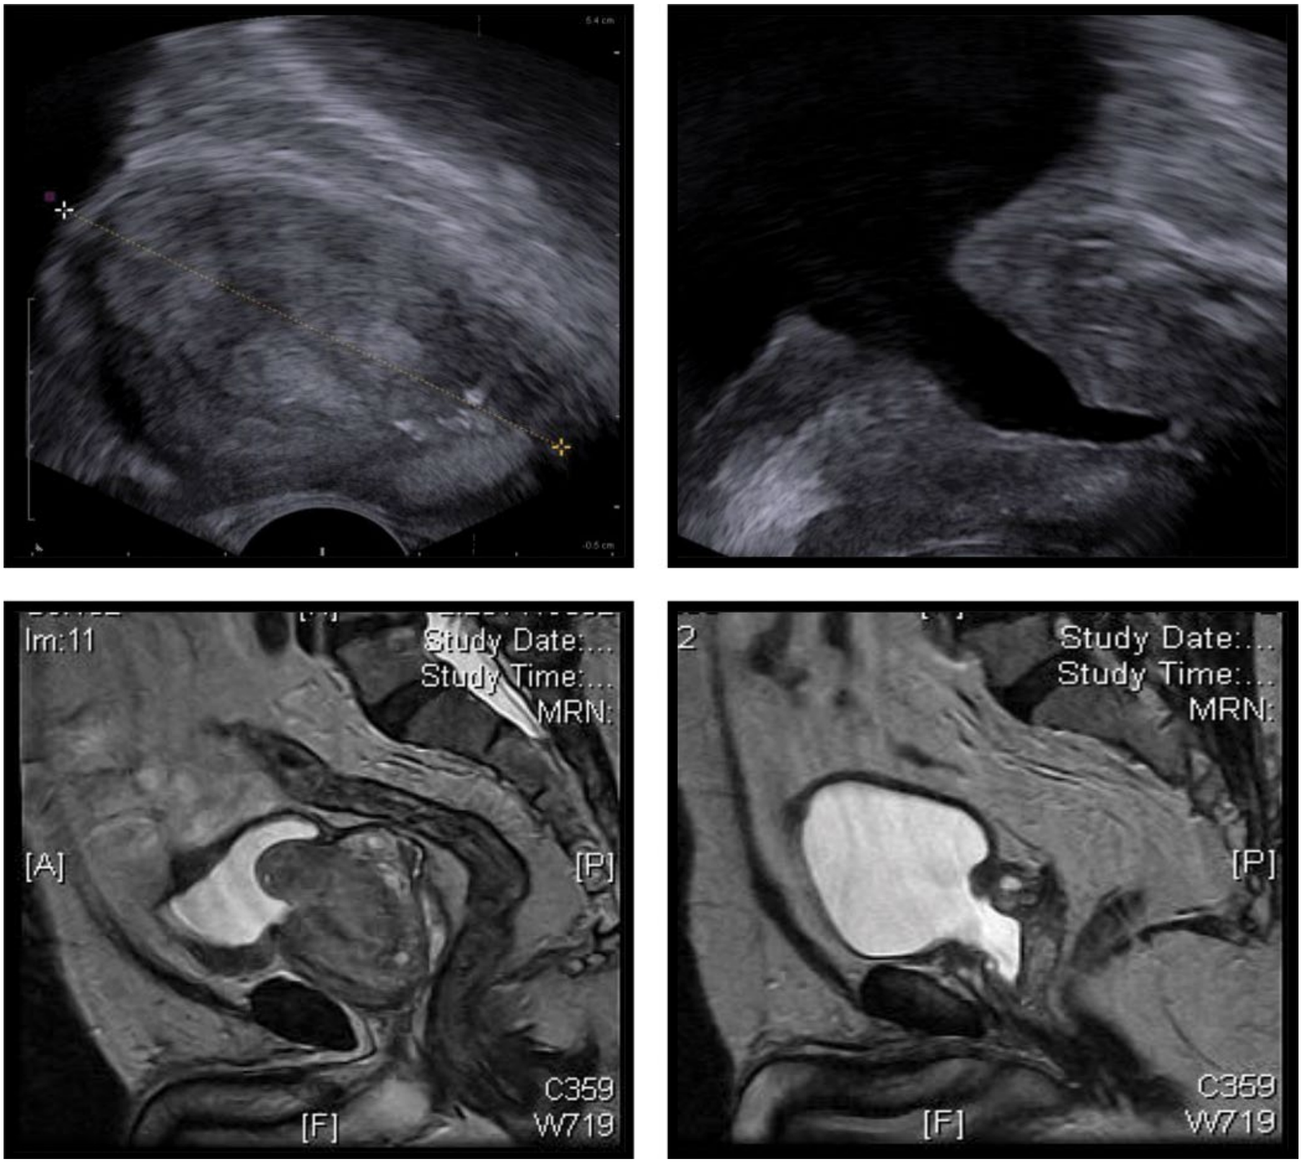

**Figure 145.2** Postoperative 82% and 84% volume reduction following holmium laser enucleation of the prostate (HoLEP) as shown in preoperative and four months postoperative (TRUS and MRI) that correlate well with postoperative PSA reduction of 79% and 83%.

## Durability

Sufficient data prove HoLEP's durability for most prostate sizes at long-term follow-up (Figure 145.3).

In a report on a total of 1216 HoLEP procedures and after a median follow-up of 7.6 years (1–14 years), 52 (4.3%) patients needed reoperation for recurrent lower urinary tract symptoms, including 13 (1.07%) for residual/recurrent adenoma, 14 (1.15%) for BNC, and 25 (2.05%) for *de novo* urethral stricture. In multivariate regression, smaller prostate size (<62 ml), PSA reduction <50%, and history of previous prostate surgery were significantly associated with recurrence of adenoma. BNC was significantly associated with smaller glands (<54 ml), while longer operative time and postoperative catheterization were significantly associated with urethral stricture. Kaplan–Meier curve demonstrates post-HoLEP freedom from reoperation of 96.9% at 5 years and 95.1% at 10 years [45]. Long-term reports on the need of reoperation for recurrent infravesical obstruction following HoLEP are summarized in Table 145.1 [18, 31, 32, 39, 46–49].

## Learning curve

HoLEP has been limited by its steep learning curve, a limitation often stated by the urologists. HoLEP requires longer training than standard TURP.

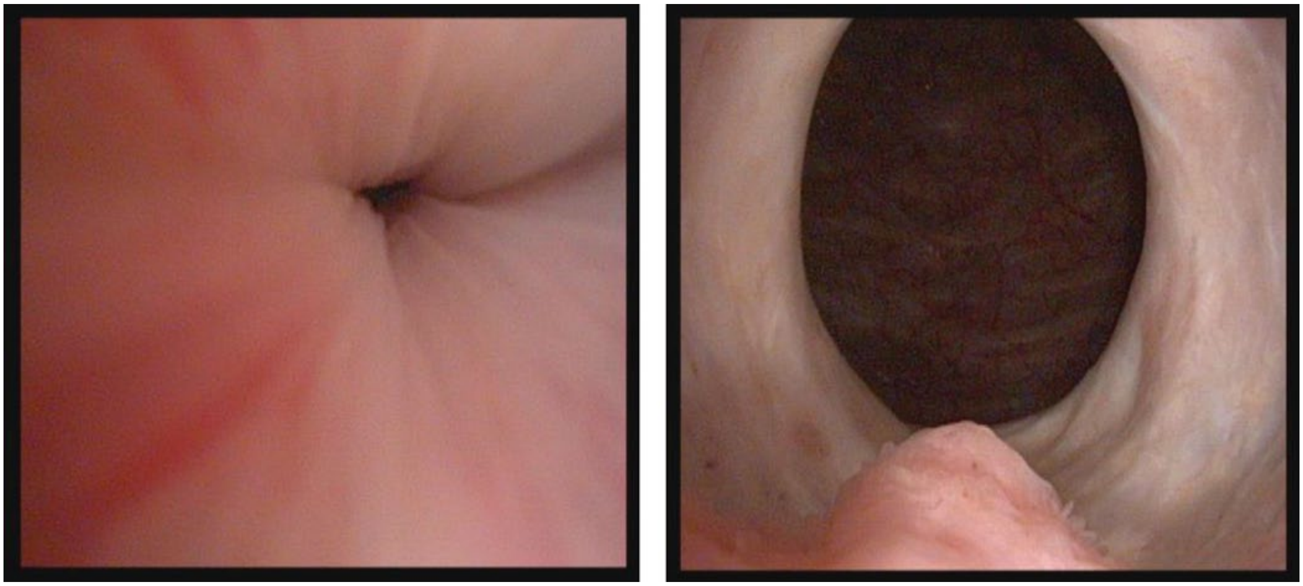

**Figure 145.3** Cystoscopic view 6 years after HoLEP.

**Table 145.1** Short- and long-term follow-up and reoperation rates.

| | Study type | Mean prostate size (ml) | No. of pts | Follow-up duration | Bladder neck contracture (%) | Urethral stricture (%) | Residual/regrown adenoma (%) |

RCT, randomized controlled trial.

Extensive experience with transurethral surgery and the supervision of an experienced urologist are mandatory to master this technique. In particular, the initial apical enucleation and incision of anteroapical mucosal attachments of the lateral lobes are difficult to master.

El-Hakim and Elhilali presented the initial experience of a senior urology resident with HoLEP. He treated 27 patients with a mean prostate size of 54.8 g under the supervision of an experienced urologist. His overall results were comparable with those reported for the supervisor. They found that an average of 15–20 cases was needed for the trainee to feel confident with the technique [50]. However, Shah et al. reported that an endourologist inexperienced with HoLEP could perform the procedure with reasonable efficiency after about 50 cases, with an outcome comparable to that of the experts [51]. A higher incidence of complications, including capsular perforation and stricture urethral stricture, was seen in first 50 cases, with enucleation efficiency reaching a plateau after 50 cases. There was no significant difference in the functional parameters between the first cases and the last 62 cases.

Seki et al. also showed that significant relief of symptoms and urodynamic parameters could be achieved even very early in urologist's experience [52]. However, the authors concluded that enucleation efficiency was likely to be associated with a learning curve of up to 50 cases, as the average enucleation efficiency was 0.29 g/min for the first 10 cases but 0.75 g/min by the 70th case.

Elzayat et al. performed a retrospective study evaluating 118 patients who underwent HoLEP and compared the results for the first 50 patients with a later group of patients [53]. There was no significant difference in the enucleation and morcellation times in both groups. However, the retreatment rate after 5 years follow-up in the earlier group was higher (8% vs. 1.4%).

New practitioners need a high volume of cases to become familiar with this technique. Urologists who do not treat enough cases to maintain a reasonable operative frequency will have a longer learning curve that could be reflected in their complication rate [54]. We feel that it is also important in the learning process for the procedures to be carried out within a short interval, so as to build on experience rather than starting from the beginning each time.

### Cost efficacy

HoLEP for treatment of large BPH seems to be more cost effective than simple open prostatectomy, both in developing and developed countries. Salonia et al. carried out prospective comparison of the inpatient cost of HoLEP versus simple open prostatectomy in 63 patients. They concluded that HoLEP is associated with significant hospital net cost savings compared to open prostatectomy. They found that the hospitalization cost of HoLEP was 9.6% less than that for open prostatectomy. The cost reduction is mostly related to the shorter hospital stay and the significant reduction of blood loss, which eliminates the need for blood transfusion [55].

Elshal et al. carried out matched-pair analysis comparing costs of HoLEP and open prostatectomy for treatment of large prostates in limited healthcare resources systems. Two years after adopting the technique and accounting for the laser capital equipment cost, they found that HoLEP costs for the hospital were equal in the first three months after procedure to those for open prostatectomy. Significant hospitals cost savings are anticipated in subsequent cases [6] once the capital costs are amortized.

The initial high cost investment in the capital equipment when adjusted as a per case cost would be markedly balanced with good flow of cases, particularly with the versatility of Ho:YAG laser as an effective lithotripter.

### Future perspectives

One of the weaknesses remains the efficiency of the morcellation for prostate tissue retrieval following HoLEP, which is still not yet optimized and needs further research and innovation. Different laser power settings could be tested for the process of enucleation, and learning modules are needed for wider adoption of the procedure among urologists.

## Conclusions

Different types of lasers have been used to perform laser prostatectomy and give comparable and durable result similar to TURP with minimal morbidity, short catheterization time, short hospital stay, and low reoperation rate with no significant complications. The holmium laser has been effectively used for many urologic applications. HoLEP seems to offer the most favorable functional outcomes in terms of subjective and objective parameters with no prostate size limitation. Emerging data have confirmed this technique to be durable with an overall low reoperation rate. For other modalities, long-term follow-up and randomized comparative studies are still needed to confirm the effectiveness and durability of each technique.

## Introduction

Traditionally, the gold standard for treatment of benign prostatic hyperplasia (BPH) has been the electrocautery-based transurethral resection of the prostate (TURP). TURP, however, is associated with several complications and side-effects, including fluid absorption, electrolyte imbalance, intraoperative and postoperative bleeding, and inadequate resection. Laser therapy has several advantages over standard TURP, including technical simplicity and the absence or minimization of complications such as intraoperative fluid absorption and bleeding. Laser therapy has proven to result in shorter hospital stay and recovery for patients. Theoretically, less bleeding and irrigant absorption allows laser prostatectomy to treat larger glands with less physiologic stress, further suggesting a role for laser therapy in patients with a high burden of coexisting medical disease. An increasing number of practicing urologists are performing laser prostatectomies on patients with symptomatic BPH. Furthermore, the techniques and lasers used for laser prostatectomy are constantly evolving. To fully understand the mechanism of laser interaction with prostate tissue, some basic laser principles must first be understood. We will review the mechanisms of laser–tissue interaction and then provide a comprehensive review of the 532 nm laser prostatectomy.

## Laser physics

The word “laser” is derived from an acronym, standing for “light amplification by simulated emission of radiation” (LASER) [1]. An external energy source is used to excite electrons in a medium with an inherently large population of unstable electrons, causing the electrons to reach a higher energy state, called a metastable level. As the electrons return to ground state, they release an amount of energy equal to that initially absorbed, resulting in the spontaneous emission of photons [1–3]. Unlike normal white light, which is made up of the entire visible electromagnetic spectrum, laser energy is monochromatic (i.e. all of its photons originate from the same energy level transition with both spatial and temporal coherence) [1–3]. In addition, laser rays are parallel to each other and hence do not converge or diverge unless reflected or focused by a lens or mirror. However, when transmitted through flexible fibers by internal reflection, the laser beam will become divergent as it exits the fiber.

Laser energy affects tissue by inducing coagulation, vaporization, or even a mechanical tearing of tissue [4]. Power directly influences the temperature level reached and the speed with which a surgical effect is achieved. In general, a temperature of greater than 50°C is required to produce a coagulative effect, while a temperature of greater than 100°C is required to produce a vaporization effect. Medical laser sources can possess a number of power outputs ranging from 20 to 180 W.

Power density, defined as power per unit area ($P/A$), represents the most important parameter that expresses the strength of the laser at a fixed location. Fibers with narrowly divergent beams will have a much higher power density than fibers with widely divergent beams due to the difference in the size of target areas. As a corollary, this also implies that maximum power density arises when the tip of a laser fiber is almost in contact with tissue (i.e. at the distance where divergence is minimized) [1–3, 5, 6].

## Laser–tissue interaction

Four major interactions occur when laser energy is applied to human tissue: reflection, scattering, penetration, and absorption.

### Reflection

Up to 50% of the incident energy of a laser beam is reflected away. After the initial reflection, the remaining energy is then transmitted through the tissue for a specific distance, depending upon the type of laser used as well as the particular type of tissue being treated. After absorption, the laser energy is then converted to thermal energy, or heat.

### Scattering

As laser energy strikes the irregularities of a tissue surface, diffuse reflection, also known as scattering, occurs. Scattering may occur in either forward or backward directions. The amount of scatter that occurs depends on tissue characteristics such as water content, cell constituents, and pigments. Scattering also depends on the resonant absorption and re-emission of radiation by the atoms of the receiving tissue, as well as the diffraction or radiation of laser energy in directions away from the line of propagation. As a result of scattering, a laser beam does not merely continue to penetrate in a straight line but dissipates its energy within the surrounding area, beginning when it hits the first tissue interface and continuing to create a zone of heat along the path of the beam.

### Penetration

Alternatively, laser energy may penetrate tissue. The depth of penetration depends on its wavelength and the composition of the receiving tissue. Penetration is often described by "extinction length," the depth of penetration of an incident beam beyond which only 10% of the initial beam energy is left (i.e. 90% absorption). Thus, after one extinction length, 10% of the beam will penetrate further, whereas after two extinction lengths, 1% of the beam will penetrate further, and so on.

### Absorption

Finally, laser energy may be absorbed by tissue. Absorption of laser energy is often described by "absorption length," the depth of tissue through which 63% of the incident beam energy is absorbed. It is important to note that the different components of living tissue absorb different laser energy wavelengths in variable fashions. Water, constituting 75–85% of soft tissue, absorbs 532 nm laser energy very poorly, resulting in deep penetration of the laser beam into tissue. Pigments such as hemoglobin, bilirubin, and melanin absorb 532 nm energy very efficiently. Finally, carbon, an abundant constituent of all living tissue, is a final breakdown product of pyrolysis and represents a strong absorber of all wavelengths of laser energy.

## History of the 532 nm laser

The original 532 nm laser was a potassium titanyl phosphate (KTP)-based laser system that contained a KTP crystal through which a 532 nm wavelength was generated. This had a different interaction with prostate tissue from its parent, the neodymium:yttrium–aluminum–garnet (Nd:YAG) [7]. The 532 nm wavelength is selectively absorbed by hemoglobin, which acts as an intracellular chromophore. The 532 nm laser energy can be fully transmitted through aqueous irrigants into the cell, where it is absorbed by hemoglobin, which is then rapidly heated, leading to vaporization of prostate tissue. The short optical penetration associated with this wavelength confines its high-power laser energy to a superficial layer of prostate tissue that is vaporized rapidly and hemostatically, with only a 1–2 mm rim of coagulation. The thin coagulation zone arises as a result of the quasi-continuous emission characteristics of the 532 nm laser. Typically, continual irradiation of a single point causes heat to diffuse into deeper tissue layers, causing coagulation wherever there is enough convection thermal energy for protein denaturation but insufficient energy for vaporization. These selective characteristics led to the use of the 532 nm laser in prostatectomy as "photoselective vaporization of the prostate" (PVP).

### The 60 W laser systems

Some of the first studies designed to test the efficacy of higher power 60 W KTP lasers first began their experimentation with both *in vivo* and cadaveric canine studies [8]. These initial canine studies were capable of providing evidence to support the 60 W laser's ability in not only vaporizing the tissue, but minimizing any simultaneous coagulation effects. Malek et al. described the first human trials in 10 patients using the 60 W KTP laser [9]. Mean operating time for the procedure was approximately 29 minutes. The results demonstrated no postoperative incidences of urinary retention and no transurethral resection syndrome. This study showed all patients were catheter-free within 24 hours of the procedure. After 24 hours, maximum renal flow rate ($Q_{max}$) had significantly improved by 142% (8 ± 1.3 ml/s vs.

19.4 ± 8.4 ml/s, $P = 0.003266$). These initial results suggested promise at three months follow-up.

In 2000, a larger study of 55 patients followed patients using the 60 W KTP laser [10]. Mean operating time was 44 minutes. At 2 years follow-up patients showed statistically significant improvements in postoperative American Urological Association Symptom Index (AUA-SI) scores (mean 14, 82% improvement), $Q_{\max}$ (mean 29.1 ml/s, 278% improvement), and PVR (27 ml, 75% improvement). After the procedure, all patients were catheter-free within 24 hours. Furthermore, no patients required recatheterization, nor did anyone experience transurethral resection syndrome. Although many patients used antiplatelet agents (at least half), hematuria was negligible. Overall, the results showed that PVP with 60 W KTP was as effective as TURP.

### The 80 W laser systems

The use of 60 W KTP was less than ideal due to its low power, which limited the size of the prostate that could be resected. In order to achieve the desired tissue ablation, the 80 W KTP laser system was introduced. It is interesting to note that to preserve a thin coagulation zone while maintaining high vaporization efficiency, laser pulsing was incorporated into the 80 W higher power KTP laser system. A high-frequency modulation of laser light generates a continuous stream of short micropulses with a duration of 4.5 ms and a peak power of 280 W (i.e. 3.5 times the average laser power of the regular 80 W laser). The short duration of the micropulses does not allow time for heat to diffuse from the superficial layer, thus confining energy to a small volume of tissue, a situation referred to as thermal confinement. As each micropulse generates a very fast temperature increase inside tissue, the tissue water is not only rapidly vaporized but the surrounding tissue matrix is torn apart, allowing for efficient removal of prostate tissue. Continuous bladder irrigation is thus required to cool the tissue as well as to provide a clear aqueous medium for laser light to be transmitted to target tissue without energy loss.

Initial experiments utilizing the 80 W KTP laser began with with *ex vivo* animal models [11]. Twenty perfused porcine kidneys were used to model human prostate tissue. The high-power resection was compared to traditional TURP-like resection and it was found that 80 W KTP showed a statistically significant decrease in hemorrhage ($P < 0.0001$). This demonstrated that bloodless ablation of tissue was possible.

Hai and Malek investigated the first human trials using 80 W KTP laser prostatectomy [12]. A total of 10 patients were followed for 1 year postoperatively. Mean operating time was 19.8 minutes. Patients experienced statistically significant improvements in AUA-SI score (23.2–2.6), quality-of-life (QOL) scores (4.3–0.5), $Q_{\max}$ (10.3–30.7 ml/s), and postvoid residual volume (PVR) (137.6–3 ml). Furthermore, there was a 27% reduction in prostate volume. No patients in the study experienced postoperative urinary retention, infection, incontinence, or erectile dysfunction; none subsequently developed bladder neck contractures or urethral stricture. Interestingly, two patients did not require catheterization following the procedure. One patient actively taking anticoagulants did experience mild transient postoperative hematuria, which required recatheterization for 24 hours. De Nunzio et al. showed in 150 patients that 80 W KTP laser was effective in decreasing storage and voiding symptoms of 81.8% and 90.9%, respectively, at 12 months [13]. Consistent with other published series, these studies further support the procedure's safety, efficacy, and durable improvements on International Prostate Symptom Score (IPSS) and QOL [14].

The 80 W KTP/532 nm laser was also tested on large prostates by Sandhu et al. [15]. Sixty-four men with BPH and prostates with volumes of at least 60 ml (mean 101 ml) underwent vaporization with the 80 W KTP laser. The mean operative time was 123 minutes. The IPSS decreased from 18.4 to 6.7 at 12 months; $Q_{\max}$ increased from 7.9 to 18.9 ml/s, while PVR decreased from 189 to 109 ml. No transfusions were required nor was there evidence of postoperative hyponatremia. All 62 patients were discharged within 23 hours.

Pfitzenmaier et al. conducted a comparative study between vaporization of prostates greater than or equal to 80 ml (39 of 173 patients) and those smaller than 80 ml [16]. PVP was discovered to be safe and effective in prostates greater than or equal to 80 ml [16]. One caveat was that reoperation was higher in the larger prostate cohort. Another study by Rajbabu et al. evaluated 54 patients with prostates greater than 100 ml who underwent 80 W KTP laser prostatectomy [14]. The mean operating time was 81.6 minutes. The mean catheterization for patients was 23.0 hours. Mean urinary flow rate improved from 8.0 to 19.3 ml/s from three months to 24 months postoperatively [14]. PVP, IPSS, QOL, prostate specific antigen (PSA), and prostate volume all showed statistically significant improvements. No complications were reported. In one study, 76 patients with a prostate size of greater than 70 ml were randomized to TURP or 80 W laser prostatectomy [17]. Procedure time was shorter for the TURP group. Hospitalization stay and catheterization time were significantly shorter in the laser group. TURP favored prostate volume reduction as well as significant improvements in IPSS, PVR, and $Q_{\max}$. In addition, reoperation rate was higher in the laser group.

Ruszat et al. randomized 396 patients to either 80 W laser prostatectomy or TURP [18]. Interim 24 months follow-up data found the rates of intraoperative bleeding

(3% vs. 11%), blood transfusion (0% vs. 5.5%), capsule perforations (0.4% vs. 6.3%), and early postoperative clot retention (0.4% vs. 3.9%) were significantly lower in the laser group. There was no significant difference in IPSS and PVR. After 12 months, size reduction was greater in the TURP group (66% vs. 44%) and the rate of repeat procedure was greater in the PVP group (6.9% vs. 3.9%, not significant).

Bouchier-Hayes et al. reported data on 120 patients randomized to undergo TURP or 80 W laser PVP [19]. At 12 months equivalent improvements in IPSS and flow rates were demonstrated. Length of hospitalization, length of catheterization, and adverse events were lower in the laser group. In a nonrandomized study, Bachmann et al. studied 101 patients who underwent either TURP or laser prostatectomy. Perioperative morbidity and symptom improvement was equivalent in the groups at six months [20]. An Australian study had similar results when comparing patients randomized to either 80 W laser prostatectomy or TURP [21]. Both groups showed a significant increase in mean urinary flow rate, improvement in IPSS scores, and no difference in sexual function at 1-year follow-up.

Guo et al. conducted a study evaluating 5-year follow-up after the use of 80 W KPT GreenLight laser vaporization of the prostate in comparison to TURP [22]. The purpose of this study was to compare long-term results of both procedures in comparison to safety, efficacy and long-term durability. This was a two-center nonrandomized prospective study. One hundred and twenty patients underwent PVP and 80 underwent TURP. At 60 months follow-up 30 patients from the PVP arm and 31 patients from the TURP arm were available for analysis [22]. There were no statistically significant differences in IPSS, QOL, $Q_{\max}$, and PVR between the two groups [22]. Those receiving 80 W KTP had a higher reoperation rate due to urethral stricture, bladder neck contracture, and persisting and recurrent adenoma [22].

There have been a number of studies evaluating the long-term outcomes of 80 W KTP laser prostatectomy. Te et al. investigated the use of the 80 W KTP laser in laser prostatectomy in the first large multicenter study. A total of 145 patients were included in the study with long-term follow-up [23]. Overall, there were significant and durable improvements in AUASI scores, QOL scores, $Q_{\max}$, and PVR 12 months postoperatively. Mean AUA-SI scores declined from 24 to 1.8 at 12 months; mean QOL scores improved from 4.3 to 0.4, $Q_{\max}$ from 7.7 to 22.8 ml/s, and PVR from 114.2 to 7.2 ml. Mean prostate volume, as determined by ultrasound, decreased from 54.6 to 34.4 ml. The mean operation time was 36 minutes with no patient requiring a blood transfusion. More than 30% of patients were sent home without a catheter; those with postoperative catheters had them removed in a mean of 14 hours. Approximately 8% of patients experienced mild-to-moderate dysuria that lasted more than 10 days, 8% had transient hematuria, and 3% had postoperative retention. Of the 56 men who were potent prior to the procedure, 27% experienced retrograde ejaculation but none of them experienced impotence.

Ruszat et al. published the largest series of 80 W KTP laser prostatectomies. At a single center, 500 patients underwent PVP, including 45% taking oral. Three years postoperatively, 26.2% of patients were included in the analysis. Mean AUA-SI, PVR, and QOL were significantly improved compared to results at baseline. At 60 months, the retreatment rate was 6.8% and reoperation rate was 14.8%. Urethral and bladder neck strictures were observed in 4.4% and 3.6% of patients, respectively, comparable to the rates in TURP [24]. Te et al. reported a multicenter long-term follow-up in 139 patients who underwent 80 W KTP laser prostatectomy. At 3 years, 33.8% of patients were included in the follow-up and improvements in symptom relief and urinary flow rate were durable [25]. The overall retreatment rate for this cohort was 4.3%.

The safety of 80 W KTP laser prostatectomy has been studied in patients at high cardiopulmonary risk, and demonstrated excellent results due to a robust hemostatic profile and perioperative hemodynamic stability of the procedure. Reich et al. performed 80 W laser prostatectomy on 66 patients with an American Society of Anesthesiology Score of 3 or greater [26]. Of these patients, 29 were being treated with ongoing oral anticoagulant or had a severe bleeding disorder. Throughout the study, no patients presented with major complications during or following the procedure and no patients required blood transfusions. Despite this, within 12 months, two patients required reoperation due to recurrent urinary retention. Mean improvements in IPSS (from 20.2 to 6.5) and peak flow (from 6.7 to 21.6 ml/s) were durable at 12 months.

The final safety aspect of the 80 W KTP laser to be studied in detail was its use in anticoagulated patients at high risk for clinically significant bleeding. Twenty-four anticoagulated patients with BPH were treated with laser prostatectomy using the 80 W KTP laser [27]. Eight were on warfarin, 2 on clopidogrel, and 14 on aspirin. Eight (33%) of these patients had had a previous myocardial infarction; 7 (29%) cereberovascular disease, and 7 (29%) peripheral vascular disease. No patients developed clinically significant hematuria postoperatively and none developed clot retention. No patients required blood transfusions, nor were there any thromboembolic events. Follow-up revealed a decrease in IPSS from 18.7 to 9.5, as well as an increase in $Q_{\max}$ from 9.0 to 20.1 ml/s at 12 months.

PVR decreased from 134 to 69 ml at one month but this was not statistically significant beyond that time point. All patients underwent PVP safely without any adverse thromboembolic or bleeding events. However, more energy and time were required for lasing per gland size in these patients [28].

## The 120 W laser systems

The 120 W is similar to the 80 W KTP laser system, but it evolved to a higher power system (HPS) capable of 80–120 W. The laser emits the same 532 nm wavelength, with the same hemostatic properties as the 80 W KTP laser [29], but uses a different crystal. The 532 nm 80 W KTP laser is created by passing a 1064 nm Nd:YAG laser beam through a KTP crystal. In contrast, the 120 W HPS 532 nm wavelength is created by passing a Nd:YAG laser beam through a lithium triborate (LBO) crystal. The 532 nm LBO-based system also has a beam that is better collimated than the KTP beam.

The use of the 120 W 532 nm laser was first evaluated using animal models. Lee et al. first investigated the use of the 120 W laser in five male beagles [30]. PVP was performed in antegrade fashion through a suprapubic cystotomy at 40, 80, and 120 W settings for three distinct firing periods (5, 10, and 20 seconds) at unique locations in the prostate. The 120 W HPS consistently vaporized more tissue per unit time, while the depth of coagulation (1.2–2.5 mm) was decreased compared to the lower powered systems. Kang et al. compared the use of the 120 W HPS laser to the 80 W HPS laser in 96 specimens of bovine prostate tissue [31]. The 120 W HPS laser vaporized bovine prostate tissue more efficiently than the 80 W KTP laser and coagulation was equivalent. Lee et al. advised caution with the higher power setting, especially at 120 W due to the potential higher risk of capsular perforation and bladder wall perforation [30]. In addition, higher power provides more efficient vaporization with less hemostasis, and as a result, utilization of the lower power coagulation setting is important in achieving hemostasis.

Heinrich et al. used blood-perfused porcine kidneys to determine the ablation capacity, hemostatic properties, and coagulation depth of a 120 W 532 nm laser compared to an 80 W laser [32]. The 120 W LBO laser offered a significantly higher tissue ablation capacity compared with the conventional 80 W KTP laser. The increased efficacy of the 120 W laser device was accompanied by a higher bleeding rate and a slightly deeper coagulation zone.

Woo et al. published one of the first studies evaluating the efficacy of 120 W 532 nm laser prostatectomy in humans [33]. In a multicenter prospective study, 305 patients with BPH underwent laser prostatectomy using the 120 W HPS laser. Study results showed an increase in $Q_{\max}$ as well as decreases in PVR, IPSS scores, and prostate volume from baseline to follow-up. All of these parameters were significant ($P < 0.001$) in all patients. A subgroup analysis was done in three groups of patients: those in retention ($n = 63$), on anticoagulation ($n = 67$), and with prostates ≥80 ml ($n = 52$). Complications were comparatively low in all groups.

In another study by Al-Ansari et al. 120 patients with BPH were randomized to either TURP or 120 W 532 nm laser [34]. Baseline characteristics for both groups were comparable. After 36 months of follow-up, a total of 55 patients in TURP and 54 patients in 532 nm laser groups completed the study. The mean operative time was significantly shorter for TURP. Compared to preoperative values, there was significant reduction in hemoglobin and serum sodium levels at the end of TURP only. In the PVP, no major intraoperative complications were recorded and none of the patients required blood transfusion. Of those patients in the TURP group, “12 (20%) required transfusion, 3 (5%) developed transurethral resection syndrome, and capsule perforation was observed in 10 patients” [34]. Significant improvement was observed in $Q_{\max}$, IPSS, and PVP compared with preoperative values. The degree of improvement was comparable in both groups at all time points of follow-up. Storage bladder symptoms were significantly higher in PVP. Reoperation was required in one TURP patient and six PVP patients ($P < 0.05$). Lukacs et al. conducted a similar study using GreenLight HPS 120 W and TURP. A total of 70 men were randomized to receive 120 W and 69 were randomized to receive TURP [35]. IPSS scores could not be demonstrated to be noninferior. The mean length of hospital stay was significantly shorter in those in the PVP group 1 (interquartile range (IQR) 1–2) versus 2.5 (IQR 2–3.5), respectively ($P < 0.0001$) [35]. Other uroflowmetry clinical values were comparable across both groups [35].

Zang et al. conducted 3-year follow-up after 78 patients underwent PVP using a 120 W system [36]. The patient’s urinary characteristics and QOL scores drastically improved following the procedure. “At 36 months, the average percentage of improvements compared with baseline was as follows: IPSS, 60.2%; QOL, 80.9%; $Q_{\max}$, 138.7%, and PVR, 82.6%” [36]. Patients showed a 50.4% reduction in prostate volume when compared to perioperative results. Complication rates were relatively low with only 6.7% needing reoperation [36]. Similarly, Cho et al. evaluated the GreenLight HPS 120 W system in 68 patients and analyzed their results retrospectively for up to 3 years [37]. At 3 years, 58.8% patients maintained improvements in IPSS, $Q_{\max}$, and prostate volume [37].

### The 180 W laser systems

Compared to the 120 W laser systems, the 180 W laser was developed with a thicker inner core fiber, which is a water-cooled redesign high-power fiber (MoXy™ Fiber, American Medical Systems, San Jose, CA, USA) [38]. Another new modification is applied to the coagulation power mode. The new 180 W capable system delivers the lower power coagulation mode laser light in intermittent pulses. This intermittent laser pulse modality mimics the intermittent delivery of power in electrocautery coagulation for hemostasis. However, the more important utility is the ability to better utilize the fiber for contact coagulation of arterial bleeders. With intermittent pulses, laser coagulation heat on tissue contact is limited by the intermittent pulsing and continuous flow of room temperature irrigant over the tip. Finally, to improve the rate of vaporization efficiency, the power of the 180 W capable system was increased. The new system has a maximal power output of 180 W. To allow utilization of the 180 W capable system, while maintaining the power density characteristics of the 120 W system and its fiber, a new fiber design was necessary. This new fiber has a wider diameter (750 μm vs. 600 μm), which provides a wider and more efficient tissue vaporization effect. This increase in fiber diameter of 0.15 mm increases the beam area by 50%.

Malek et al. first described the 180 W system in living canines. A total of eight dogs underwent antegrade PVP. Researchers discovered this system produced a bloodless 76% larger cavity. Furthermore, this laser “vaporized tissue at a 77% higher rate and in 37% less of the time” [38]. Evaluation showed a 33% thicker mean coagulation zone compare to the 120 W laser [38]. In conclusion, the 180 W laser system had a higher vaporization rate and deeper coagulation zone with healing and tissue interactions comparable to those of the 120 W laser [38].

Bachmann et al. conducted the first study evaluating the use of the 180 W XPS laser involving a MoXy fiber in men with lower urinary tract symptoms (LUTS) secondary to BPH [39]. A total of 201 men were included in the study with a mean follow-up time of 5.8 months. All clinical parameters (IPSS, $Q_{max}$, PVR, QOL, prostate volume, and PSA) had statistically significant improvements as early as one month postoperatively ($P < 0.001$) except PVR ($P = 0.001$) [39].

Lee et al. conducted a retrospective analysis on 384 patients who underwent PVP using the 180 W XPS laser [40]. The purpose of this study was to evaluate any intraoperative or postoperative complications in patients with ongoing platelet aggregation inhibition, and oral anticoagulation [40]. Following the procedure all clinical parameters such as IPSS, QOL, $Q_{max}$, and PVR improved in both those on and those off anticoagulation [40]. At 2 years follow-up there were no significant differences between the two groups.

A few studies over the years have evaluated the 180 W laser system in comparison to the 120 W system. One study by Ben-Zvi et al. looked at the comparative effectiveness of these two laser therapies in 200 patients [41]. Eighty patients were treated with GreenLight HPS 120 W and 120 patients with GreenLight XPS 180 W. Mean operating time was shorter for those in the 180 W group (43 vs. 79 minutes). Furthermore, postoperative characteristics such as IPSS, QOL, and PVR were comparable. There were no reported differences between the groups in terms of a 30-day complication rate. Patients receiving the 180 W laser treatment had a statistically significant reduction in PSA (54% vs. 79%, $P < 0.01$) [41]. Both systems proved to be safe and effective in treating BPH obstruction. However, results of the 180 W XPS laser system suggest a more cost-effective treatment and efficient tissue removal due to shorter operating times, fiber use, and the reduction in PSA [41].

Hueber et al. conducted a global, multicenter study to evaluate the use of the 120 W and 180 W laser systems [42]. Across seven international centers, 1187 patients underwent 120 W HPS and 622 patients underwent 180 W XPS. Similarly, the 180 W laser system had a lower operating time (53 vs. 80 minutes $P < 0.01$) [42]. The larger the prostate volume the more increased the use of fiber, operating time, and laser energy. When these results were stratified according to prostate volume, researchers found that the XPS system had significant advantages over the HPS system in all operative parameter regardless of the prostate size ($P < 0.01$) [42].

In a prospective multicenter randomized controlled trial known as the GOLIATH trial, researchers investigated the noninferiority of the 180 W GreenLight XPS to TURP by evaluating patients’ IPSS and maximum flow rate at six months postoperative [43]. A total of 281 patients with benign prostatic obstruction (BPO) from 29 centers across nine European countries were enrolled in the study [43]. After randomization and those lost to follow-up a total of 134 patients received XPS and attended the six months follow-up visit. Similarly, 131 patients were assigned to TURP and attended the six months visit. At baseline, patient demographics and urodynamic characteristics were similar in each treatment group. When evaluating the primary objectives and outcomes, Bachmann et al. found the end points at six months not to be significantly different between those who had received XPS and those who had received TURP. The noninferiority was met at a $P$-value of 0.002 [43]. Furthermore, researchers found both treatment groups were consistent in their ability to make improvement in IPSS over the six-month follow-up period (XPS = 6.8; TURP = 5.6) [43]. The same noninferiority was met for $Q_{max}$ at six months with XPS = 23.3 and TURP = 24.2 ($P = 0.002$), which demonstrated comparable results in both arms [43]. At six months, patients in both treatment arms showed similar complication-free rates with XPS = 87.3% and TURP = 83.2% ($P = 0.019$) [43]. During the follow-up portion of the study, the overall complication-free rate was higher for those who had received XPS.

Although perioperative characteristics were generally comparable across treatments, researchers found patients in the XPS arm had a shorter length of catheterization, shorter hospital length stay, and a shorter time until their health was stable ($P < 0.005$) [43]. Functional results and efficiency parameters demonstrated QOL, IPSS, PVR, and prostate volume were all significantly decreased at the six-month follow-up for both treatment arms. At six months, prostate volume between groups had a $P$-value of 0.079 [43]. Over the course of the trial, 47.8% of XPS patients and 53.4% of TURP patients were free of treatment-related adverse events. A total of 117 adverse events were reported in those receiving XPS and 98 in those who received TURP. Of these adverse events, in each group the most common events documented were bleeding, urinary incontinence, and storage symptoms.

The GOLIATH trial demonstrated the noninferiority of XPS to TURP and short-term efficiency. This large prospective study showed the comparability of XPS in improving IPSS, $Q_{\max}$, and prostate volume reduction in men with LUTS due to BPO. At 2-year follow-up, Thomas et al. found that noninferiority of the procedures in the clinical parameters and complications was sustained, and that 83.6% of patients in the GreenLight XPS group and 78.9% of those in TURP remained complication-free through the 2-year follow-up [44]. Prostate volume reductions were comparable in both arms of the study [44].

Valdivieso et al. discovered in patients undergoing GreenLight XPS 180 W LBO PVP to treat BPH that increasing the energy level of the laser was able to significantly reduce PSA level by >50% [45]. These results were durable at 6, 12, and 24 months postoperative. Despite this reduction, functional outcomes showed no differences at the 2-year follow-up time point.

Altay et al. investigated the safety and efficacy of the 180 W XPS laser in men with prostates larger >80 ml [46]. A total of 68 men underwent the procedure and had follow-up at 3, 6, and 12 months postoperatively. Significant improvement was seen in IPSS, $Q_{\max}$, and PVR at 3, 6, and 12 months ($P < 0.001$) [46]. At 12 months, the average prostate reduction was 40.5%. For men with larger prostates the 180 W laser system proved to be safe and effective in treating BPH.

Since the GOLIATH trial, recent studies have evaluated the outcomes of the PVP procedure in men with large prostates [47]. In another study by Hueber et al., researchers conducted a multicenter trial to evaluate the safety and efficacy of the 180 W system [48]. A total of 1196 patients were treated and follow-up lasted for 24 months. Those patients with a prostate larger than 80 ml had a significantly higher rate of conversion to TURP when compared to those with a prostate size lower than 80 ml (8.4% vs. 0.6%, $P < 0.01$) [48]. All parameters such as IPSS, QOL, $Q_{\max}$, and PVR were significantly improved across both groups. This procedure further proved to be safe and efficacious for men independent of their prostate size.

## Patient preparation

Many patients today are routinely taking aspirin, nonsteroidal anti-inflammatory drugs (NSAIDs), and other medications that may affect platelet function. Others may be actively receiving chronic anticoagulation with agents such as coumadin. Although these patients may have raised concerns in the era of electrocautery TURP, the hemostasis associated with laser prostatectomy allows select patients to be treated without stopping or changing their medical regimen [27, 49, 50]. However, the risks of treatment on active anticoagulation therapy should be clearly stated to the patient, as the risk of bleeding will always be higher while on anticogulation medication than off it.

Age-appropriate patients should be screened with both digital rectal examination (DRE) and serum PSA levels as per AUA guidelines [51]. Prostatic abnormalities may be evaluated with transrectal ultrasound and biopsy as indicated. Such screening is important in laser prostatectomy since pathology is not adequately sampled for histologic examination [52].

A minority of patients with bladder outlet obstruction due to BPH will present with active urinary tract infection or significant pyuria. This should be treated prior to laser prostatectomy, especially since potential coagulated, nonperfused, necrotic tissue can remain *in situ* postoperatively and may become seeded with bacteria in the presence of active infection. For the typical patient who presents with sterile urine, routine antibiotic prophylaxis is recommended prior to laser resection of the prostate.

The consent for laser prostatectomy is very similar to that obtained for other transurethral operations. Patients are informed that they will require an anesthetic, and of potential complications associated with any invasive urologic procedure, such as bleeding, urinary tract perforation, infection, urinary incontinence, erectile dysfunction, retrograde ejaculation, and urethral stricture or bladder neck contracture. Finally, the patient should be informed that remaining tissue can grow back, causing recurrent voiding symptoms, and that additional prostate surgery may be required.

## Preoperative preparation

Standard patient positioning in the dorsal lithotomy position with sterile draping and cleansing preparation is used, as for routine cystoscopy or any other transurethral operation. A properly functioning laser source and compatible laser delivery fiber are required. Laser safety should be of paramount importance in the operating room. Laser energy can cause significant thermal injury to human tissues, including irreversible retinal damage. All operating room personnel and the patient must wear proper eye protection. Operating room windows should be covered to prevent the inadvertent passage of stray laser light; doors should be appropriately marked to warn outside personnel that laser energy is in use. When the laser is not being actively used, and in particular when the fiber is removed from the cystoscope and the working end lies free on the operative field, the surgeon should remove their foot from over the laser pedal and nursing personnel should close the shutter on the laser machine to prevent accidental firing, which could lead to drapes being ignited and patients burned with the beam.

## Technique

Laser prostatectomy requires local, regional, or systemic anesthesia due to the pain associated with acute laser burns to the prostatic urethra. Leach et al. have in addition described a transperineal injection technique using lidocaine and bupivacaine to achieve local prostatic and pudendal nerve blockade, which when combined with intravenous sedation may also provide adequate anesthesia to perform laser prostatectomy [53]. When using injection anesthetic, it is important to be aware of the maximum dosage as overdosing may result in significant adverse events.

Cystourethroscopy is performed with a standard 21–26 Fr cystoscope. However, laser prostatectomy requires the specialized continuous-flow cystoscopes that have been designed for laser prostatectomy. If continuous-flow irrigation is inadequate to provide a clear field of vision, a suprapubic catheter can be placed to provide continuous intraoperative irrigation flow as well as postoperative urinary drainage. Since clinically negligible fluid absorption occurs during laser prostatectomy, special irrigation solutions are not required; normal saline is relatively inexpensive, is the fluid of choice compared to osmolar solutions, and provides good visualization. Room temperature, rather than warmed, irrigation provides cooling for the laser delivery fiber, limiting thermal damage as well as prolonging the usable lifespan of fibers. The irrigant is hung 30 cm above the bladder and allowed to flow under gravity. Suction irrigation to the outflow port should be avoided, as it is unnecessary and may increase the risk of inadvertent bladder perforation. The prostatic anatomy is carefully assessed and the prostatic urethral length from the bladder neck to the proximal aspect of the verumontanum is inspected. The laser fiber is then passed through the working port of the cystoscope and visualized in the prostatic urethra in preparation for beginning laser application.

Laser energy is directed at the locations along the prostatic urethra that are obstructed, such as medial, lateral, and anterior lobe tissue. A systematic and aggressive approach to laser prostatectomy will ensure complete laser treatment of all obstructive tissue elements. Laser resection may begin with either the medial or lateral lobes, but should always begin proximally and be continued distally, working away from the bladder neck and toward the verumontanum; after the proximal prostate near the bladder neck is opened by superficial tissue vaporization, there will be improved irrigation flow for the more distal laser treatment.

Laser energy may be applied in a continuous fashion over an area, barring excessive tissue resection (e.g. perforation). PVP, the technique described for 532 nm laser prostatectomy, is often described as "painting" systematically over the surface of the prostate until a TURP-like cavity is formed. However, a more correct analogy is "mowing the lawn," since a systematic sweeping technique is utilized to remove tissue in layers. In addition, the optimal distance from the tissue is small, within one fiber cap in a noncontact technique. Excellent vaporization results in a stream of bubbles, which represent the steaming away or vaporization of tissue. The laser source is used first to vaporize the median lobe to the level of the trigone. Once a channel has been created that allows adequate irrigation, the lateral lobes are next vaporized. This is followed by apical vaporization. At the end of the PVP procedure, a cavity should be present where the adenoma once was. If bleeding is encountered during PVP, the laser setting is lowered to allow coagulation instead of vaporization and the target area is coagulated.

Optimally, the fiber tip should be held just off the mucosal surface such that a clear plane of water stands between the tip and tissue; by moving the beak of the cystoscope close to the fiber tip, the scope can be used to hold tissue away from the tip in many instances. In addition, resecting proximal before distal prostate tissue aids in freeing tissue from the fiber. Finally, when all else fails and occlusive prostate tissue must remain in contact with the metal mirror during treatment, a very slight vibratory motion of the fiber tip (i.e. no more than 1–2 mm longitudinal oscillation), combined with good water flow can keep tissue from adhering to the metal fiber tip. For all fibers with a mirror reflecting mechanism, routine cleaning of the fiber is recommended. The build-up of spattered particulate on the fiber surface during treatment can cause superheating with fiber degradation. Prophylactic cleaning between each laser application and ensuring adequate room temperature water flow throughout the duration of each individual laser application are the most important means of preserving fiber integrity.

### Vaporesection/enucleation techniques

Once the basic technique is mastered, the 532 nm laser can be used to enucleate, vaporize, and resect tissue. This technique is referred to as transurethral laser enucleation of the prostate (TLEP). The procedure allows pathology to be collected and analyzed, improves surgical debulking of obstructive prostate tissue, and increases tissue removal efficiency, shortening operative times. This advanced technique is essentially a hybrid between TURP, laser vaporization, and enucleation utilizing the 532 nm laser [54]. The technique can be quickly learned by those with prior transurethral resection skills. However, there is a learning curve to transurethral navigation of complicated and long anatomy that is clearly related to experience of transurethral resection anatomy [54]. Pathology is provided and resection/enucleation is very complete. An incision is made through the median lobe until the bladder neck fibers can be seen. Sweeping motions with the side-fire laser fiber ensure that a wide channel is made, which allows for strong flow of cooling irrigant. Incisions are made lateral to the median lobe while visualizing ureteral orifices to ensure their safety. The intervening tissue between the incisions is divided into smaller chips. Multiple vaporization–enucleation–incision cycles are made down to the fibers of the prostatic capsule. The intervening tissue is vaporized, incised, and pushed into the bladder. Apical tissue proximal to the verumontanum is carefully ablated with care to preserve the verumontanum.

Son et al. investigated the use of the HPS 120 W laser, which utilizes a modified vaporization–resection technique, known as the Seoul technique [54, 55]. The procedure involves “vaporization of the prostate along the previously outlined margins and retrieving the resulting wedge-shaped prostatic tissue” [55]. This was a retrospective study including 104 patients with BPH who had undergone PVP and a prostate volume >40 ml. Sixty-four patients received the Seoul technique and 40 patients received vaporization only. $Q_{\max}$, PVR, IPSS, and QOL scores were evaluated for both groups at 1, 3, 6, and 12 months postoperatively. These parameters after PVP compared to baseline significantly improved ($P < 0.05$) [55]. Those patients receiving the Seoul technique showed significant reduction in prostate volume per operating time, as well as lasing time and laser energy ($P < 0.05$) [55]. In both groups the complication rates were low. Son et al. proved the Seoul technique for PVP has good short-term efficacy and is a safe treatment for patients with BPH. Furthermore, this procedure shortens operating time, lasing time, and energy. It allows urologists to preserve prostatic tissue for pathological evaluation.

Gomez Sancha et al. described the use of a high-power LBO en bloc enucleation to treat BPH in patients with larger prostates [56]. The laser equipments used were a GreenLight HPS 120 W and a GreenLight XPS 180 W, with a 2090 fiber and a MoXy fiber, respectively. Patients are first placed in a lithotomy position. Next, a “26-F continuous flow resectoscope is inserted in the uretha avoiding urethal or prostatic trauma or bleeding” [56]. In stage 1, the anatomic photoselective vaporization creates a central cavity in the prostate using a standard vaporization technique. Next, stage 2, a hybrid vapoenucleation technique is employed to create grooves in order to reach the surgical capsule also known as photoselective vapoenucleation. Finally, stage 3 includes the photoselective en bloc enucleation to resect the tissue and to deliver the “adenoma ‘en bloc’ into the bladder” [56]. This technique proved to be efficient, producing “excellent vaportization and coagulation properties in prostatic tissue,” especially in larger prostates [56].

## Postoperative care

At the conclusion of laser prostatectomy, a urinary catheter is left in place to provide drainage. A suprapubic catheter may be left in place to facilitate early or repeated voiding trials if desired. Many centers routinely discharge patients following complete recovery from anesthesia, making laser prostatectomy essentially an outpatient procedure. Catheter drainage to a urinary leg bag if necessary can be maintained and easily mastered by most patients. Patients should note that if they have a history of preoperative urinary retention or detrusor hypocontractility with a large preoperative residual urine volume, they may require longer catheterization times. Postoperative management with suprapubic catheter drainage in these individuals may be ideal to allow easy or repeated voiding trials if needed.

Following catheter removal, immediate improvement in voiding may not occur. This may be due to inefficient vaporization resulting in a greater degree of coagulation necrosis. In fact, patients may have little or no change in voiding during the first 1–2 weeks postoperatively and they may experience slightly worse symptoms while the treated prostatic transition zone sloughs. During this time, patients may note a cloudy, white appearance in the urine, caused by proteinaceous material from the dissolving prostate; others may note the passage of minute particulate matter in the urine. This phase of active tissue dissolution can be associated with symptoms of mild dysuria, which are usually relieved by NSAIDs as needed. Phenazopyridine appears to be much less effective for this syndrome, but may also be used as needed. By 4–6 weeks following laser prostatectomy, most patients begin to note a significant improvement in their voiding pattern. Improvement will continue in most men for an additional 6–12 weeks and longer, until maximum voiding outcome is achieved. By three months, voiding outcomes are similar to those expected after electrocautery TURP. With the more efficient vaporization and limited coagulation necrosis with high-power 532 nm laser applications, improvement may occur as soon as a few days to a week following application, with minimal dysuria.

Because of the superior surgical hemostasis associated with laser prostatectomy, significant restrictions on physical activity are not as limiting, even in the immediate postoperative period. After catheter removal, sexual intercourse is allowed immediately if desired, but a wait of about one month is recommended postoperatively. Patients should be warned of the possibility that the ejaculate may be temporarily dark or bloody. The most significant risk from activity is hematuria, which is usually clinically insignificant but can on occasion result in clot retention requiring transient catheterization and irrigation.

Serum levels of PSA rise approximately 10-fold following laser prostatectomy, generally peaking on the first postoperative day [57]. This seemingly corresponds with the height of capillary leakage and tissue edema after the laser burn injury. By three months, we have observed serum PSA levels to be at or below baseline in more than half of our patients. Approximately 90% have returned to or are below baseline values by six months [58]. Those with significant and persistent elevations of PSA levels beyond this time probably should be evaluated for subclinical prostatic infection or occult carcinoma.

## Complications

All published studies have reported decreased morbidity associated with laser prostatectomy as compared with traditional surgical approaches. Bleeding is the main complication of traditional electrocautery TURP, often necessitating transfusion and causing associated problems such as clot retention, premature termination of the procedure, and inadequate relief of obstruction [59]. Bleeding can also result in continuous catheter irrigation and complications, such as stricture secondary to traction on the Foley catheter. Rarely, uncontrolled bleeding can even require open packing of the prostatic fossa. Poor visibility because of bleeding is also thought to be a cause of sphincteric damage and incontinence resulting from TURP. The incidence of hemorrhage requiring blood transfusion is 3.9% and this increases twofold if the amount of resected tissue exceeds 45 ml or if the resection time is longer than 90 minutes. In contrast to TURP, which cuts across the prostatic parenchyma and opens prostatic venous sinuses, laser prostatectomy seals blood vessels as it coagulates the transition zone and prevents both absorption of irrigating fluid and hemorrhage; the hemostasis associated with laser prostatectomy is thus superior, with even multiple studies of anticoagulated patients undergoing resection without bleeding complications [27, 49, 50].

Irrigant fluid absorption during electrocautery TURP results in a 2% incidence of transurethral resection syndrome because of dilutional hyponatremia, glycine-induced ammonia intoxication, or the direct toxic effect of glycine [59]. As with bleeding, fluid absorption increases with larger glands and longer resection times. Laser prostatectomy minimizes this complication, again through its sealing zone of coagulative effect on tissue which prevents fluid absorption.

The incidence of urethral stricture after electrocautery TURP is 3.1%; if bladder neck contractures are included, this figure approaches 5%. Stricture formation is thought to be secondary to trauma induced by the large size of the resectoscope as well as the use of low-intensity, coagulating current, which penetrates deeper into tissue than cutting currents. Since laser procedures do not use electrical current, the cystoscopes utilized are smaller in size, and the overall operative time is usually shorter, the incidence of stricture is lower. The incidence of reoperation for residual obstructive tissue is difficult to determine since most published series of laser prostatectomy have documented initial experiences only with this technology. Our experience is that the incidence of strictures and bladder neck contracture is higher in patients with bladder dysfunction or bladder diverticulum, or following long procedures utilizing larger diameter scopes.

Postoperative infections may also occur after TURP. The incidence of urinary tract infection following TURP is 15.5% (median) while epididymitis occurs in 1.2% [59]. Urinary tract infections have been reported in 1–20% of patients following laser prostatectomy and epididymitis in 5–7% of patients [5, 60–64]. The treatment of such infections may be more problematic in laser prostatectomies secondary to the residual necrotic prostate tissue that remains *in situ* for several weeks after laser coagulation. When this occurs, the most common manifestation is subacute prostatitis, characterized by significant and persistent irritative voiding symptoms, with mild prostatic and/or epididymal tenderness on examination, persistent pyuria, and positive urine cultures. Two cases of frank urosepsis have been reported following laser prostatectomy, both requiring TURP to remove infected necrotic prostate tissue [65]. Aggressive antibiotic therapy is therefore warranted in these patients.

Finally, retrograde ejaculation represents another potential side-effect of electrocautery TURP, occurring in up to 90% of patients. The incidence of impotence following electrocautery TURP ranges from 3.4% to 32% [66, 67], while its overall incidence following all forms of laser prostatectomy is rare.

Since its inception in 2010, the 180 W laser system has demonstrated its ability to be effective when treating patients with BPH. One study found some of the most common complications following this procedure to be: urinary tract infections (9%), dysuria (22.8%), incontinence (11.8%), and stricture (5.1%) [43]. Hueber et al. found complication rates to be similar across prostate groups with the incidence of bladder neck or urethral stricture ranging from 3.9% to 4.6% ($P = 0.66$) [48]. Rates of patients experiencing urinary tract infections postoperatively were 4.9–5.1% ($P = 0.90$) [48]. Another possible complication is resultant retrograde ejaculation. Altay et al. reported a 41.8% incidence of retrograde ejaculation, which was lower than the GOLIATH trial which reported a 64.7% incidence [43, 46]. The largest concern with using the GreenLight system has been the conversion to traditional TURP. This is due to intractable bleeding occurring in men with larger prostates. A study by Bachmann et al. reported a conversion rate of 16% in their cohort [39]. In the study by Hueber et al. the only major complication was the conversion rate to TURP for patients with prostates >80 ml as compared to those <80 ml (8.4 vs. 0.6%, $P < 0.01$) [48]. In another study, the conversion rate to TURP was 7.3%, with these patients requiring TURP loop for hemostasis [46].

## Contraindications

There are scenarios when laser coagulation of the prostate is not indicated, and where electrocautery resection may still be advantageous. These include certain cases of bladder cancer, in which acute electrocautery resection of the bladder neck or enlarged prostate may be necessary to access tumors behind the bladder neck, especially anteriorly. Rarely, this maneuver may also be needed for ureteroscopic access. In cases in which histologic assessment of the prostate for invasion by transitional cell carcinoma is required for staging of malignancy, electrocautery resection is indicated. Finally, in the uncommon case of chronic, recurring prostatitis where electroresection of the prostate may be used to remove infected tissue and/or prostatic calculi, laser prostatectomy cannot substitute for an aggressively performed TURP. In the rare case of a prostatic abscess that must be unroofed transurethrally, electrocautery resection may also be indicated.

## Conclusions

Laser prostatectomy has proved to be a safe and efficacious surgical intervention to relieve symptomatic bladder outlet obstruction. Overall morbidity contrasts favorably with standard surgical approaches. Moreover, laser technology is generally accessible to the practicing urologist. These attributes have positioned laser prostatectomy as an accepted and sometimes preferred surgical treatment of bladder outlet obstruction secondary to BPH.

# Thulium Lasers

*Andreas J. Gross & Christopher Netsch*

*Department of Urology, Asklepios Klinik Barmbek, Hamburg, Germany*

## Animal studies

The first animal studies in the field of urology with thulium:YAG (Tm:YAG) lasers were published by Theisen et al. in 2003 [1]. They demonstrated the tissue-cutting ability of a Tm:YAG laser on a pig liver with coagulation zones of 0.8 mm or less [1]. El-Sherif and King tested the ablation abilities of thulium fiber lasers on various soft tissues *in vitro*, such as muscle, cartilage, and liver [2].

In 2005, Fried reported the vaporization capabilities of a thulium fiber laser using canine prostates as an *ex vivo* model [3]. He used a mean of 88.5 ± 2.3 W of a 110 W high-power laser at a wavelength of 1.91 µm. Thus, his results may not be absolutely comparable with the commonly used Tm:YAG lasers working at 2013 nm, since absorption coefficient and penetration depth depend on wavelength and even small changes may have a relevant impact (Figures 147.1 and 147.2). With the setting used by Fried, the laser works in both a continuous wave (cw) and a chopped mode. The focus of interest in this study was the measurement of the tissue vaporization rate in a given time, which was 0.83 ± 0.11 g/min at 88.5 W laser power [3].

Thulium laser settings at 26 W were not powerful enough, however, to make efficient and accurate incisions [4, 5]. The zone of thermal damage had a wide variance of 500–2000 µm in two studies [4, 5]. Fried and Murray stated that a higher power laser could be used to deliver more energy during a shorter pulse duration, with the intention of reducing collateral tissue damage. Fried confirmed his original data in further *ex vivo* studies in canine prostates, and additionally in animal ureters and bladder neck tissue [3–5]. He was not concerned about unacceptable collateral tissue damage, which was documented to be several hundred microns of thermally damaged tissue [4].

Whereas the first *ex vivo* studies were with soft tissue, Fried also published data on urinary stone fragmentation [6]. A cw high-power thulium fiber laser operating at a wavelength of 1.94 µm was modulated to operate in a pulsed mode with an output pulse energy of 1 J, pulse duration of 20 ms, and repetition rate of 10 Hz. The fragmentation time to reduce various stones into particles of less than 2 mm was measured. In principle, a high-power cw thulium fiber laser, when operated in pulsed mode, could fragment both soft and hard urinary stones, not accounting for the time taken.

## Clinical experience with thulium laser treatment of the prostate

Clinically, thulium lasers were studied first in otolaryngology, pneumology, gynecology, gastroenterology, and neurosurgery [7–9]. An early paper in the field of urology was published in 2005 by Xia et al. [10]. They performed a low-power vaporesection of benign prostate hyperplasia (BPH) using a 50 W Tm:YAG laser [10]. Subsequently, laser treatment of the prostate has evolved to be the main field of thulium laser applications in urology (Figure 147.3).

### Vaporesection

Xia et al. reported their initial experience with the Tm:YAG laser on 30 patients using the so-called “tangerine technique” for BPH treatment [10]. They sliced the prostate in tangerine-like pieces *in situ* and extracted these mechanically with a syringe. The ability of the Tm:YAG laser to cut prostate tissue chips small enough

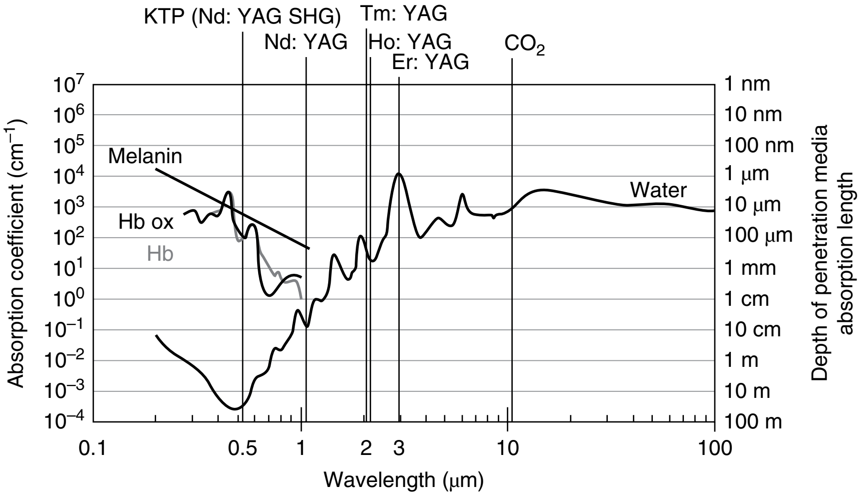

**Figure 147.1** Absorption spectrum for melanin, hemoglobin (Hb; oxygenated hemoglobin, Hb ox), and water in comparison to selected laser wavelengths and carbon dioxide.

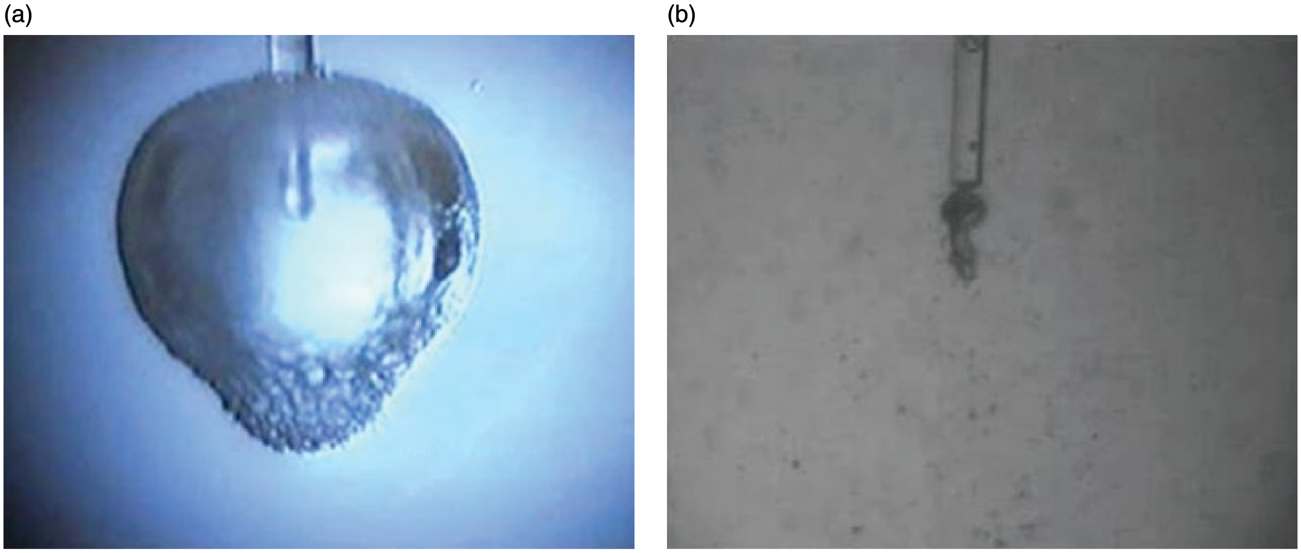

**Figure 147.2** (a) Large steam bubbles in a pulsed laser (holmium laser; 2 J, 32 W). (b) Small steam bubbles in a continuous wave laser (2 µm, 50 W).

for the resectoscope sheath was an important difference from the previously introduced lasers, especially the holmium:YAG (Ho:YAG) laser, which cannot cut or resect. This is the most important difference between thulium and holmium lasers, since the application and surgical techniques of thulium lasers in BPH treatment are very similar to those of holmium lasers.

The patients in this first paper by Xia et al. had a mean prostate volume of 58 ml, an average International Prostate Symptom Score (IPSS) of 19, and a maximum urinary flow rate ($Q_{\max}$) of 8.0 ml/s [10]. The Tm:YAG laser was used at 50 W. During a mean operating time of 56 minutes, an average of 1 g tissue was removed per minute. This tissue retrieval rate was in the range of contemporary holmium laser enucleation of the prostate (HoLEP) series of that time, which reported enucleation rates of up to 0.71 g/min [11]. In the first series by Xia et al., neither perioperative blood transfusions nor postoperative bladder irrigation were necessary [10]. The Foley catheter remained *in situ* for 1–3 days. Three months after surgery, $Q_{\max}$ (24.7 ml/s) and IPSS (7.1) had improved significantly. No cases of new onset of impotence were found. These data were confirmed at 1-year follow-up [12].

In 2007 Bach et al. reported their initial results with 54 patients being treated with 70 W Tm:YAG high-power vaporesection of the prostate (mean volume 30.3 ml) and the subsequent 1-year follow-up [13]. At that time, holmium laser enucleation of the prostate had already been described [14]. However, one disadvantage of the

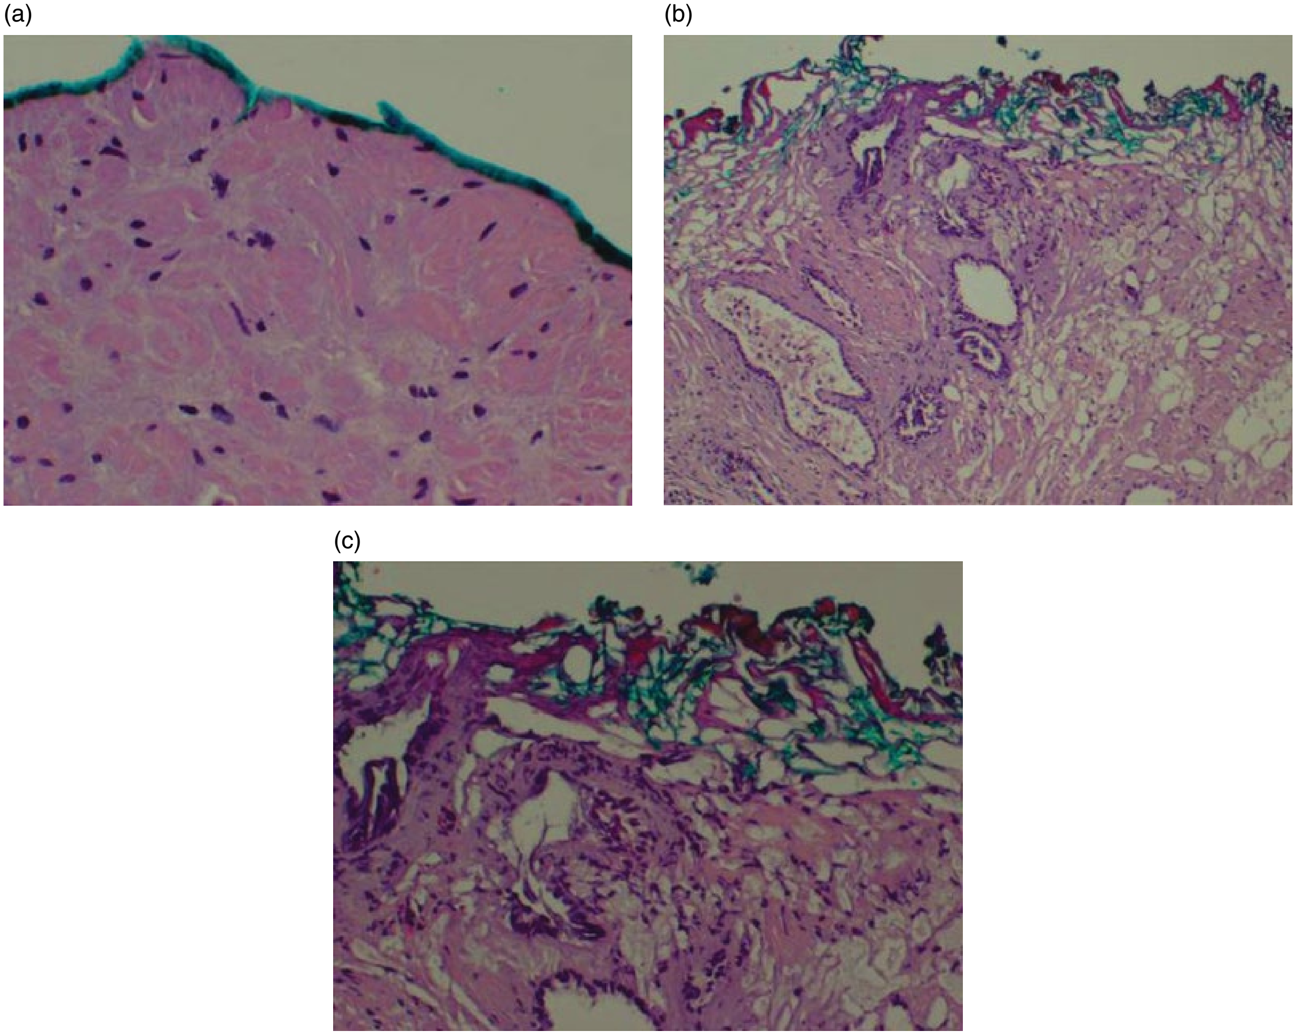

**Figure 147.3** Human prostate following treatment with a 70 W, 365 µm fiber thulium laser in contact mode. (a) Magnification × 20; (b) × 40; (c) × 100.

enucleation procedure was the difficulty in removing the tissue from the bladder: either a mechanical tissue morcellator was used for removal of the enucleated lobes off the bladder or the so-called "mushroom technique" [15]. In the latter, the prostate is left attached by a pedicle at the bladder neck and the tissue is then resected with a monopolar or bipolar loop into transurethral resection of the prostate (TURP)-like chips. Vaporesection is a protocol where small chips are produced with a Tm:YAG laser and washed out with a syringe, similar to the standard resection technique. In the series of Bach et al., mean preoperative $Q_{\max}$ was 8.1 ml/s after exclusion of 14 patients with acute urinary retention (AUR). In this first study, removal at a resection speed of 0.6 g/min was achieved, which increased with growing experience to 1.5 g/min. Mean catheter time was 1.7 days (range 1–3 days). Blood transfusions were not required in any patient. However, six patients had urinary tract infections (UTIs) with irritative voiding symptoms 1–2 weeks postoperatively, which required antibiotic therapy. At 1-year follow-up, no bladder neck stricture or urethral stenosis had occurred. IPSS, $Q_{\max}$, postvoid residual urine (PVR), and quality of life (QOL) had improved significantly at 1-year follow-up and continued to do so at 18 months follow-up [13, 16].

After these reports from clinical practice, a systematic *ex vivo* evaluation of the thulium laser was performed by Wendt-Nordahl et al. [17]. The ablation capacity and hemostatic properties were tested at different power settings in a previous well-established model of the isolated blood-perfused porcine kidney. Histologic examination of the ablated tissue was used to compare changes after thulium laser treatment with results after TURP and use of a 80 W potassium titanyl phosphate (KTP) laser. At a power setting of 70 W, the thulium laser achieved a higher tissue ablation rate (average 6.56 g in 10 minutes).

This is, of course, far more than is achieved in clinical practice, since no time is lost for surgical orientation. The KTP laser ablated 3.99 g of tissue in the same time, whereas with TURP 8.28 g was removed in 30 seconds. The bleeding rates were 0.16, 0.21, and 20.14 g/min, respectively. The corresponding depths of the coagulation zones were 264, 666.9, and 287 μm, respectively. In conclusion, this study showed that the thulium laser offered a higher tissue ablation capacity and similar hemostatic properties to the KTP laser, and in comparison to TURP the bleeding rate was significantly reduced. The smaller quantity of removed tissue compared to TURP was due to the fact that the thulium laser was used for vaporization only.

The first prospective randomized prospective trial was performed by Xia et al. [18]. One hundred patients were randomized into two groups: 52 underwent Tm:YAG laser resection using the tangerine technique mentioned above and 48 underwent standard TURP. Preoperative assessment included IPSS, QOL, $Q_{\max}$, PVR, International Index of Erectile Function-5 (IIEF-5), and urodynamic studies. Those parameters were re-evaluated at 1, 6, and 12 months. Catheterization time was significantly shorter in the laser group (45.7 vs. 84 hours; $P < 0.0001$). Blood loss was less in the laser group and hemoglobin was lower (0.92 vs. 1.46 g/ml; $P < 0.001$) than in the TURP group. IPSS, QoL, Qmax, PVR and IIEF-5 as well as urodynamic studies did not reveal any significant difference between the groups. Both groups benefitted from the respective interventions.

Results from a larger series of patients ($n = 200$), also with larger prostate sizes (up to 120 g), were published by Mattioli et al. [19]. They used a 70 W laser with bare-ended and side-firing laser fibers. Bare-ended fibers used with the cw thulium laser are applicable for all BPH protocols, such as vaporization, vaporesection, and vapoenucleation; however, side-firing fibers are used for vaporization only. Mattioli et al. advocated the use of both fibers. They used a laser that enabled switching with a foot pedal between the two modes, and preferred to resect first and vaporize thereafter. In patients with prostates smaller than 35 g, vaporization was performed; in those with prostates larger than 35 g vaporesection and/or vaporization was performed. Mean catheterization time was 16 hours (range 12–72 hours). The efficacy of the procedures was evaluated with $Q_{\max}$, PVR, and the IPSS questionnaire. The authors concluded that clinical outcome was comparable with TURP and the KTP and Ho:YAG lasers.

Szlauer et al. have published a DVD on the vaporesection procedure with a thulium laser [20]. This DVD shows the main steps of the technique as introduced by Bach et al. [13]. The laser fiber is moved semi-circumferentially from the verumontanum towards the bladder neck, thereby undermining tissue and cutting chips. Szlauer et al. reported the results from 56 nonconsecutive patients. The mean procedure time was 60 minutes, postoperative irrigation was necessary in 19 of 56 patients (29%), and the mean time of catheterization was 23 hours. The decrease of hemoglobin was at 0.2 mg/ml until the day of discharge. Mean $Q_{\max}$ improved from 8.1 to 19.3 ml/s ($P < 0.001$) and the PVR decreased from 152 to 57 ml ($P < 0.05$). This study included the first report of the need for blood transfusions (two patients, 3.6%) after thulium laser procedures. Two patients needed recatheterization postoperatively. After a mean follow-up of nine months, IPSS improved from 19.8 at baseline to 8.6 ($P < 0.001$). During the learning curve, persisting obstructive symptoms in four patients necessitated a second procedure. Szlauer et al. chose TURP, while a few other authors have reported satisfactory second procedures for persisting complaints utilizing the Tm:YAG laser in a resection technique [21]. During the learning curve for a new technique, such as any laser procedure, it is appropriate to fall back on the standard procedure. Two patients in this series developed postoperative complications (one urethral stricture and one bladder neck contracture).

Over time, vaporesection has become less important as there is a strong trend towards enucleation techniques – no matter what energy source is used. But vaporesection still has its uses in thulium laser treatment of the prostate as it is an important step during the learning curve from vaporization to complete enucleation.

## Vapoenucleation

Following their work on vaporesection with thulium lasers, Bach et al. looked at holmium laser enucleation and implemented thulium lasers for this technique (so-called vapoenucleation of the prostate) in 2009 [21]. This represented a development because vaporesection and, indeed, any kind of pure vaporization, was limited to smaller glands, as the amount of tissue that can be removed by vaporization techniques is time limited, necessitating prolonged operating times with increasing prostate volumes. It became obvious that for larger glands tissue removal using mechanical morcellators must be an integral part of the procedure. Bach et al. again used a 70 W laser to remove the tissue, as in the previously described three-lobe technique in HoLEP [22], in 88 patients with a mean prostate size of 61.3 g. In brief, the procedure starts with the marking of the distal resection border close to the verumontanum. Turner–Warwick-like incisions down to the surgical capsule are made at the 5 and 7 o'clock positions up to the previously marked distal resection border. Then the entire median lobe of the prostate is enucleated. After that, the first lateral lobe and consequently the second lateral lobe are enucleated and positioned into the bladder for morcellation. After enucleation, tissue is morcellated within the bladder [22].

In 2015, Kim et al. published a variation of enucleation, the "all-in-one" technique [23]. The mean operative time was 82.1 ± 33.3 minutes and the mean enucleation and morcellation times 52.7 ± 21.7 minutes and 8.2 ± 7.0 minutes, respectively. The mean resected tissue weight and decrease in hemoglobin were 36.9 ± 24.6 g and 0.4 ± 0.8 g/dl, respectively. These results are consistent with two- or three-lobe techniques [23].

Bach et al. demonstrated the feasibility of laser enucleation of the prostate using the thulium laser, as previously shown for Ho:YAG lasers [21]. The authors discussed the advantages of this laser in comparison with open simple prostatectomy and Ho:YAG laser enucleation [21]. The operative time was 72 minutes, of which laser time (beam on) was 32.4 minutes. The remainder of the operative time, as in any other transurethral procedure, was taken up by instrumentation, catheterization, and morcellation. According to the authors, a suprapubic trocar could be used to perform a low-pressure procedure. An average of 127 kJ of laser energy was applied. An average of 31.7 g of prostatic tissue was available for histologic examination. The percentage of tissue lost through vaporization was estimated to be 30%, and it should be noted that the amount of retrieved tissue is often underestimated because of this. The average Foley catheter time was the same as in other laser procedures, being 2.1 days. Three patients (4.2%) had persistently high residual urine after removal of the Foley catheter and were discharged with suprapubic catheter *in situ*. At 1-year follow-up, improvements in urodynamic parameters appeared to be durable, with an increase in $Q_{\max}$ from 3.5 to 23.3 ml/s ($P < 0.001$) and decrease in PVR from 121 to 33 ml. IPSS decreased from 18.4 to 6.8. Early complications were UTI in 6.8%, hematuria in 5.6%, and the need for immediate retreatment in 2.2%. One patient developed an urethral stricture. Postoperative dysuria was reported in 27%, a rate similar to that with any other ablative procedure in the prostate [24]. At 48-month follow-up, $Q_{\max}$, PVR, IPSS, and QOL were still significantly better compared with baseline ($P < 0.001$). Bladder neck contractures and urethral strictures developed during follow-up in 1.6% and 0.8% of the patients, respectively. No patient had to be retreated during follow-up for recurrent prostatic tissue [25].

A slight variation of thulium vapoenucleation of the prostate (ThuVEP) is called thulium laser enucleation of the prostate (ThuLEP). ThuLEP is blunt transurethral anatomical enucleation of the prostate using the beak of the resectoscope with Tm:YAG laser support [26]. A large series with 1080 patients treated with ThuVEP confirmed the previously published data; median prostate size was 51 ml and median operation time was 56 minutes. Median enucleation time in this group was 32.5 minutes. Median resected tissue weight was 30 g, confirming that 60% of tissue should be resected. Incidental carcinomas were detected in 5.5% of the patients. $Q_{\max}$ (8.9 vs. 18.4 ml/s) and PVR improved significantly at discharge ($P < 0.001$). Clavien 1 and 2 complications occurred in 24.6% and Clavien 3 in 6.6%. There was only one Clavien 4 complication (0.09%). The overall complication rates decreased significantly over time with increasing individual and institutional experience of the ThuVEP procedure [27].

Open prostatectomy has been considered the standard technique for larger glands. It is effective and durable, but the rate of severe complictions is high. In one of the last large series of open prostatectomy, Serretta et al. in 2002 reported a complication rate of 15% [28]. Although the average overall complication rates for open prostatectomy and Tm:YAG laser prostatectomy appear to be comparable, the rates of severe unexpected complications, bleeding-related complications, and transfusion drop significantly with Tm:YAG laser prostatectomy. This is particularly important because surgical treatment for BPH tends to be performed in an older age group. Transfusion rates of 8.2–26.5% have been reported with open prostatectomy [29]. In a recent series of 2648 patients, Bach et al. differentiates different groups of prostate sizes and compares their blood loss during the respective procedure (Table 147.1) [30]. The infection rate was 8.6% in open prostatectomy, whereas in a series of 687 patients treated with thulium laser, Netsch et al. reported an infection rate of 4.66% [31].

To overcome these bleeding-related complications with open prostatectomy, HoLEP was introduced as a size-independent technique for BPH treatment [14]. Elzayat and Elhilali reported a blood transfusion rate of 1.3% after HoLEP in patients with BPH and a mean prostate volume of 126 ± 45.1 ml [32]. To overcome some disadvantages of the Ho:YAG laser, thulium lasers are now used for the same indication, mimicking the HoLEP technique. The main advantage of the thulium laser is the cw-mode that allows clear cuts and therefore better vision of the surgical site [21, 24]. The incision in the tissue is clear and the penetration depth is shallow. Thus, the surgeon can cut at any desired point and is not dependent on finding the exact layer of the surgical capsule between the adenoma and peripheral zone [21, 24]. If this path is lost, it may be easier to return to the preferred layer using the thulium laser or stop the enucleation procedure if the layer of enucleation is lost and change to vaporization of the tissue. For those in the early stages of learning the enucleation protocol, this may be a major problem with any other kind of laser. Clear cuts with a thulium laser therefore lead to a shorter learning

**Table 147.1** Transfusion rate in relation to resected tissue in transurethral resection and thulium vapoenucleation of the prostate, stratified according to preoperative transrectal ultrasonography volume.

| Preoperative TRUS volume | Procedure | Resected tissue (g) | Transfusion rate (%) |
|---|---|---|---|
| <40 ml ($n$ = 790) | TURP | 14.6 ± 27.5 | 1.3 |
| | ThuVEP | 15.9 ± 11.8 | 1.7 |
| 40–79 ml ($n$ = 1102) | TURP | 31.0 ± 34.6 | 2.8 |
| | ThuVEP | 35.1 ± 18.1 | 2.0 |
| ≥80 ml ($n$ = 480) | TURP | 38.5 ± 23.2 | 7.1 |
| | ThuVEP | 70.8 ± 33.6 | 7.0 |

TURP, transurethral resection of the prostate; ThuVEP, thulium vapoenucleation of the prostate; TRUS, transrectal ultrasonography.

curve [33]. El-Hakim and Elhilali reported that a minimum of 50 cases have to be undertaken to achieve a reliable learning curve for HoLEP [34]. For thulium laser treatment with either simulator or mentor-based training a learning curve of 50 and 32 patients, respectively, seem to be sufficient to achieve safety during the procedure [35, 36].

The results of long-term follow-up for HoLEP, which is the earlier introduced technique, are available [37], but there is no reason to presume that outcomes for thulium laser enucleation would differ. Netsch et al. submitted an abstract for publication with a prospective randomized trial comparing HoLEP with ThuLEP [38]. In this prospective randomized trial, 96 patients were enucleated with either one of the two lasers, and no difference was found in any of the evaluated parameters.

In conclusion, both procedures give equivalent and satisfactory immediate micturition improvement with low perioperative morbidity. Thus, thulium laser enucleation appears to be repeating the experience with Ho:YAG lasers, but with an improvement in the ability to resect and consequently a shorter learning curve. With both ThuLEP/ThuVEP and HoLEP, simple open prostatectomy becomes obsolete.

At this stage, four surgical protocols using thulium lasers for the treatment of BPH have been introduced: vaporization, vaporesection, vapoenucleation, and mechanical blunt enucleation with Tm:YAG laser support. The following discussion considers subgroups of patients, cost, and recent developments in the standard protocols.

## Patient subgroups

Bach et al. evaluated the feasibility and efficacy of thulium laser enucleation of the prostate in 65 patients with an indwelling transurethral catheter due to recurrent urinary retention secondary to BPH [39]. They were compared to 143 patients scheduled for the same procedure, but without catheterization for urinary retention. Both groups were comparable in terms of clinical parameters. At discharge, mean $Q_{\max}$ and PVR had improved in both groups and were similar. The incidence of bleeding was similar, but UTI were more frequent in the catheterized group. Since up to 40% of patients scheduled for surgery for BPH can develop AUR, this study has an important impact on decision-making regarding the adequate procedure. Carmignani et al. confirmed these data in their series of 93 patients [40]. Compared to other laser techniques treating similar groups of patients, the thulium laser appears to offer advantages [41].

With an aging population, the percentage of patients on oral anticoagulants is high and increasing. In a large group of 2648 patients undergoing surgical treatment of BPH, Bach et al. had 36.7% receiving some form of anticoagulation therapy. Interestingly, the transfusion rate remained stable at a low level during a time when the percentage of patients under oral or systemic anticoagulation doubled. In 61.4% of the patients, anticoagulation was not stopped before surgical intervention, because bridging may alter the risk of thromboembolic complications [30]. Ong et al. showed that regular users of anticoagulants who had enoxaparin bridging are at a higher risk of both perioperative bleeding and thromboembolic complications [42]. Maccione et al. observed 76 patients with oral anticoagulants. Thirty-five discontinued the treatment with oral anticoagulants 10 days before thulium vaporesection of the prostate (ThuVARP) and 41 were treated under ongoing therapy. No differences between the procedures with regard to surgical time, hospital stay, or functional outcomes were noted [43]. In a next step, Netsch et al. performed a three-center retrospective matched-paired comparison of patients treated with either ThuVARP or ThuVEP under ongoing oral anticoagulants [44]. They concluded that both ThuVEP and ThuVARP were equally efficacious in patients on oral anticoagulants. The only difference noted was a higher $Q_{\max}$ at six months for patients treated with ThuVEP. All other functional parameters measured were not significantly different.

The impact of any surgical or interventional treatment of benign prostatic obstruction (BPO) on erectile function is an important issue. In his review, Li et al. worked up 18 randomized clinical trials with 2433 patients. Pooled data of the four various laser systems revealed that all surgical procedures for BPO except photoselective vaporization of the prostate did not have any negative impact on erectile function when preoperative and postoperative IIEF-5 scores were compared directly [45]. Tiburtius et al. prospectively evaluated 72 patients who underwent ThuVEP. At 12-month follow-up, they found a marginal nonsignificant erectile function improvement [46]. Carmignani et al. followed up 180 patients after ThuLEP and reported in up to 56% of the patients preservation of antegrade ejaculation [47]. These numbers are a little better than those published by Yee et al. with a preservation of 44% in their cohort of 113 patients treated with ThuVARP [48].

## Economic issues in practice

Scientific data on the cost-effectiveness of surgical techniques for BPO are scarce. A wide array of different international health systems have to be compared. From a medical point of view, the following parameters should be addressed: operating time, concomitant medication, hospital stay versus outpatient treatment, operation success, reoperation rate, and work incapacity. On the other hand, providers of certain surgical techniques have to deal with costs of purchase and maintenance: Is it better to buy or to lease? Is it possible to share? How much disposable material comes (or goes) with each procedure? Is the main instrument a multiple purpose device or designed for a solitary operation? With these numbers it is possible to calculate how many cases have to be done to achieve a financial break-even point.

## Recent developments and modifications to the standard procedure

Early studies with thulium lasers were performed with 70 W laser output, but, pushed by developments in other laser systems, thulium lasers with 120, 150, and 200 W have been introduced and have made it necessary to reassess the ablative and hemostatic properties [49]. In particular, it has to be clarified whether higher power would create a deeper zone of tissue coagulation and tissue penetration, which might lead to an increased risk of collateral damage. Bach et al. recently showed that the amount of tissue ablation increased with increased power output, but with increasing fiber diameter (800 µm fiber instead of 550 µm), the depth of the cut decreased [49]. As shown by Wendt-Nordahl et al. in their previous study [17], tissue ablation with the thulium laser appeared to be more effective than reported for other systems. This study indicated also that the bleeding rate did not increase with the higher power output. In contradiction to that, it has been shown that bleeding rates increase at higher power settings in other laser systems [50, 51]. There were no differences in the clinical outcomes as shown in 28 patients treated with a 200 W Tm:YAG laser [52].

A more interesting consideration with the higher power laser is the effect on deeper tissue layers, leading to a lower possibility of histologic assessment or even collateral damage. Using standard H&E staining, the extent of the coagulation zone with the 70 W thulium laser is reported to be 0.36 mm with the 550 µm bare-ended fiber and 0.49 mm with the 800 µm fiber [49], which is smaller than that reported for other laser systems [51]. Deep tissue penetration is responsible for obstructive necrotic tissue, leading to a high reoperation rate [53]. Dissipation of heat does not end at the border of the coagulation zone.

There have been two recent reviews of laser treatment for prostates, including thulium lasers. Herrmann et al. included articles published between 1995 and 2009 encompassing 3669 patients [54], and concluded that most contemporary laser treatment modalities provide similar $Q_{\max}$ improvement compared to open surgical treatment. To differentiate one treatment from another, they advocated comparative computer urodynamic investigations.

Bach invited all authors of scientific thulium laser publications to define the terminology for different surgical techniques, and he proposed the use of this terminology to ensure a homogeneous nomenclature [55]. In brief, the authors recommended the following terms: ThuVaP for vaporization of the prostate, ThuVaRP for resection, ThuVEP for enucleation in combination with vaporization, and ThuLEP for blunt enucleation with laser support, respectively (Table 147.2).

## Thulium lasers in the treatment of urinary tract conditions

There is less experience using thulium lasers for the treatment of strictures or transitional cell carcinoma (TCC) of the upper and lower urinary tract.

**Table 147.2** Proposed nomenclature for thulium laser protocols.

| Technique | Basic principle | Consensus nomenclature |
|---|---|---|
| Vaporization | Destruction | Tm:YAG vaporization of the prostate (ThuVAP) |
| Vaporesection | Resection into small tissue chips (to be washed out) | Tm:YAG vaporesection of the prostate (ThuVARP) |
| Vapoenucleation | Enucleation in combination with vaporization of the median and lateral lobe | Tm:YAG vapoenucleation of the prostate (ThuVEP) |
| Enucleation | Blunt enucleation with laser support | Tm:YAG laser enucleation of the prostate (ThuLEP) |

## Bladder neck contractures

Bach et al. reported the treatment of bladder neck contractures in 14 patients using a 70 W 2 μm cw Tm:YAG laser [56]. The unsatisfactory results with other interventions, such as bladder neck incision either by cold knife or electrocautery, stents, or balloons, led them to try thulium lasers. The use of lasers for the treatment of strictures was not new, but due to their operational mode and disadvantageous wavelength, they were of limited use; the coagulation zone was suspected of causing recurrent strictures. The technical features and biologic effect of thulium lasers make them more appealing for the treatment of strictures. It should be remembered that the thulium laser can cut through any kind of tissue, no matter whether perfused or scarred. Bladder neck incision also offers a good way to learn the handling of thulium lasers, as the procedure is short, bleeding does not occur, and orientation *in situ* is clear.

In the study by Bach et al., bladder neck incision was carried out successfully in all patients [57]. Mean operative time and catheter time were short: 7 minutes and 6.5 hours on average, respectively. The $Q_{max}$ improved from 9 to 25 ml/s after two months and 23 ml/s after 12 months, while the American Urological Association Symptom Index (AUA-SI) score improved from 22 to 8. Two patients developed restenosis during that time.

In a much larger series of 238 patients [56], Guo et al. confirmed the positive results of Bach et al. There were no complications such as significant blood loss, urine leakage, or rectum injury. $Q_{max}$ increased from 3.2 ml/s preoperatively to 16.7, 18.7, and 19.2 ml/s directly after removal of the catheter, three and five months after the intervention, respectively. IPSS improved from 28.3 to 7.1 to 5.3. Forty-three patients developed restenosis and seven were incontinent 1–3 weeks after catheter removal. All cases of incontinence were temporary. Mattioli et al. published their experience with a single laser incision for treatment of congenital bladder neck sclerosis [58]. This procedure was performed successfully in 214 patients with either unilateral or bilateral incision. At 1-year follow-up, antegrade ejaculation was unchanged in 179 patients (91.3%). All other parameters on sexual function were not permanently changed. Even women with bladder neck obstruction underwent thulium laser incision. In a direct comparison between an electric and a thulium resection group, thulium resection was advantageous with regard to intraoperative blood loss and postoperative catheterization time. There was no urethral stricture or stress incontinence in the thulium group as compared to three patients with either one of these conditions in the electric resection group [59].

## Ureteral strictures

Thulium lasers have been used in a completely new technique for the treatment of subtotal ureteral strictures [60]. Using a combination of endourology and fluoroscopy, the laser fiber is pulled through the stenosis "blindly." In these extreme cases of strictures, the restenosis rate was as high as 38.8%, although the rest of the group were spared from major surgical intervention. Thus, although the results of thulium laser intervention for this application are practicable, they are not superior to any other procedure.

## Transitional cell carcinoma

Endoscopic management of upper urinary TCC has been assumed to have an important role in diagnosis and treatment. The well-known disadvantages of laser treatment also became obvious in the treatment of this entity; either the depth of laser penetration was too great or the pulsed mode disrupted the tissue to be treated. Consequently, Scoffone et al. suggested thulium lasers as an option in this type of procedure [61]. Defidio et al. compared the use of holmium and thulium lasers for the treatment of upper tract TCC in 59 patients [62]. Thulium lasers had a noninferior recurrence-free survival as compared to Ho:YAG laser ablation, but they showed better median parameter performance scores in precision, fiber-tip stability, bleeding, and mucosal perforation.

Gao et al. has reported the use of thulium lasers for the treatment of recurrent bladder tumors [63], a condition for which transurethral resection of the bladder (TURB) is considered to be the standard procedure. According to the authors, histology may not necessarily be required in these cases. They performed thulium laser resection of bladder tumors (ThuRBT) via a flexible cystoscope in 32 patients. All patients were treated successfully with no hemorrhage, obturator nerve reflex, or bladder perforation. Biopsies taken after the procedure revealed no residual tumors. During the first year of follow-up, local and heterotopic recurrences were found in three and six patients, respectively. The accumulated recurrence rates at 3, 6, and 12 months were 9%, 22%, and 28%, respectively.

The first paper on Tm:YAG laser *en bloc* mucosectomy for accurate staging of primary bladder cancer was published in 2011 [64]. Wolters et al. demonstrated the feasibility of resecting bladder tumors *en bloc* with detrusor muscle in the specimen. A re-resection after six weeks was negative for residual TCC in all six patients. Muto et al. confirmed these results in their series of 32 patients [65]. After a mean follow-up of 16 months the recurrence rate was 14.5%, all locations being outside the site of the first resection. Even in larger tumors of a mean diameter of 2.5 cm *en bloc* enucleation proved to be possible [66]. The advantage of laser treatment of bladder cancer is that it may be performed as outpatient treatment, with less blood loss, no occurrence of obturator nerve reflex, and, therefore, a reduced bladder perforation rate.

## Other transurethral procedures

There has been recent interest in the use of thulium lasers in other transurethral procedures, due to their shallow depth of penetration and good coagulation abilities. Mattioli et al. reported on their initial experience with partial nephrectomy, either open or laparoscopically, in nine patients [67]. In six patients, the big vessels were clamped, while in three they were not. Mean tumor size was 3.5 cm and mean operative time was 135 minutes for the open procedure and 210 minutes for the laparoscopic procedure. Blood loss was 260 ml in the open procedure and 156 ml in the laparoscopic procedure. One case was done under renal hypothermia. The authors were able to outline the precise dissection as there was an absence of bubbles and minimal formation of gas during the laparoscopic procedure. The laser coagulated vessels up 1.6 mm, which allowed good sealing of the surface. Operative time was relatively short because suturing of renal parenchyma was not required. Gruschwitz et al. have also reported successful results for Tm:YAG laser-supported partial nephrectomy [68]. Their data were confirmed by a study on 10 patients with nephron-sparing surgery by Sciarra et al. [69].

# The Prostatic Urethral Lift Procedure Using UroLift Implants: Novel, Minimally Invasive Therapy for Benign Prostatic Hyperplasia

*Daniel B. Rukstalis*

*Department of Urology, Wake Forest University School of Medicine, Winston Salem, NC, USA*

## Introduction

A male infant who was born in the United States in 2013 would be expected to live until age 80, with many men living substantially longer than that length of time. Given the variety of improvements in both preventative and interventional healthcare, it is likely that this man will remain active and avoid many of the usual concerns, such as cardiac disease, that have caused disability in previous generations of men. However, it remains likely that this man will experience prostatic growth over time that results in noticeable voiding symptoms. In fact, it is fair to consider benign prostatic enlargement from prostatic hyperplasia as an obligate condition of the aging male [1]. This argument is supported through analysis of published autopsy series in which the prevalence of histologic benign prostatic hyperplasia (BPH) has been shown to increase with age from 23% in the fifth decade of life to 87% by age 80 [2]. In addition, the prevalence of clinically identified prostatism, currently identified as lower urinary tract symptoms (LUTS), correlates closely with the development of histologic BPH [3].

The estimated volume of the prostate has also been shown to increase as men age from a normal 20 g size at age 20 to a median volume on autopsy of 33 g with 4% of prostate glands measured as over 100 g in men over the age of 70 [4]. Although the experience of voiding dysfunction is not directly correlated with the estimated size of the prostate these findings further support the expectation of progressive prostatic enlargement with aging.

Since it has been established that BPH is more common in older men and is associated with an increased risk of intervention for the associated symptoms from infravesical obstruction it may be valuable to estimate the number of men who could be in need of any interventions. The average life expectancy for men in 2001 was 76.8 years, which at that time represented an increase of 27.5 years since the year 1900 [5]. The overall death rate has continued to fall with an increase in life expectancy to 78.2–82.7 years in 2010, with a likely further 8–10 year increase by 2050 [6, 7]. In addition, men are living longer without other medical disabilities, suggesting that a growing number of healthy older individuals will experience progressive voiding dysfunction from BPH and desire intervention beyond medications [8].

Although BPH represents the pathophysiologic disorder for which many therapeutic interventions have been developed it is actually the health of a man's bladder that determines his experience with the prostatic enlargement. There is little information regarding bladder health, in general, and the length of time a man's bladder will remain healthy once obstructed by an enlarged prostate. The development of a standardized patient-reported questionnaire regarding voiding symptoms has provided a surrogate marker for overall bladder health in aging men [9]. This instrument was not developed to diagnose BPH but rather to objectively measure bladder-related voiding symptoms and to monitor the progression or improvement in these symptoms with intervention [10]. Information from the International Prostate Symptom Score (IPSS) questionnaire has demonstrated an age-related increase in LUTS for both men and women, with the most severe symptoms present in older men [11]. This suggests that age independently impacts bladder heath but prostate enlargement likely plays an additional role in men. Morphologic studies in animals and humans also suggest that infravesical obstruction from BPH alters bladder smooth muscle and connective tissue with likely adverse consequences [12]. Ultrasound analysis of bladder weight also appears to identify detrusor-related consequences of prostatic enlargement. Kojima found that the ultrasound-measured bladder weight improved

toward normal values in 29 of 33 men by 12 weeks following a prostate-directed bladder outlet procedure [13]. Interestingly, men with bladder weights higher than 80 g did not improve, suggesting that there is a threshold of bladder deterioration beyond which improvement is unlikely despite intervention.

Therefore, as more men age without disability but with obligate prostatic enlargement, it can be predicted that the demand will grow for therapeutic options that can treat the bladder outlet obstruction and maintain a healthy bladder. Importantly, these therapies should successfully manage the obstruction without toxicity and with acceptable cost. Pharmacologic agents have been developed, such as alpha-adrenergic antagonist agents or 5-alpha reductase inhibitors, that can reduce the urinary voiding symptoms but do not alter the underlying physiologic obstruction [14]. It appears that the mechanical obstruction necessitates a mechanical solution. The prostatic urethral lift (PUL) procedure using the UroLift® implant system (Neotract, Inc., Pleasanton, CA, USA) may represent that solution.

## Anatomic considerations for the prostatic urethral lift procedure

Histologic BPH develops within the transition zone of the prostate, which represents a region around the prostatic urethra that gradually enlarges to compress the urethral lumen. Although the exact cause of the pathologic enlargement is incompletely understood it likely involves inherited genetic factors, hormonal dysregulation, and ongoing inflammation that induces the release of proliferative mediators [15]. Urodynamic testing has identified urethral obstruction secondary to both compression by the enlarged prostate as well as a constrictive component that may be related to specific tissue factors such as fibrosis [16]. Traditional extirpative interventions all involve a reduction in the prostate volume (directly with resection or indirectly with thermal ablation) that creates a more open prostatic urethral lumen with clear demonstration of improved voiding parameters. It is the associated toxicity of these procedures that has created a clinical need for a novel therapeutic approach.

The PUL technique using the UroLift implant system is conceptually designed to also create a more open prostatic urethral lumen that can overcome both the compressive and constrictive aspects of BPH. The stromal capsule that surrounds the prostate gland is strong, while the prostatic parenchyma is sponge-like and able to be compressed. The placement of a transprostatic implant between the capsule and the urethral urothelium can compress the intervening parenchyma and create an open lumen.

The specific location for placement of the implants is designed to avoid injury to the bladder neck, ejaculatory ducts, posterolateral neurovascular structures, and the rectum. The prostatic parenchyma is compressed in an anterior and lateral direction that creates an open anterior channel through the prostatic lumen.

## Equipment

The PUL procedure has been designed as an endoscopic technique that can be performed under a variety of anesthesia conditions. The equipment includes a 20 Fr rigid cystoscope with a 2.5 mm 0° endoscope (currently manufactured by Karl Storz, Tuttlingen, Germany) with a longer custom bridge that allows direct visual placement of the cystoscope into a man's bladder.

The permanent UroLift implant consists of a nitinol capsular tab attached to an adjustable length of polyethylene terephthalate (PET) monofilament that traverses the prostatic parenchyma. The inner urethral endpiece is constructed of stainless steel and is applied to the appropriately tensioned PET suture. The delivery system is currently a single-use device that contains all components of one implant and is delivered through a spring-loaded 19 gauge needle under direct endoscopic guidance. The 0° endoscope is inserted through each individual delivery device. A photograph of the equipment is provided in Figure 148.1.

## Surgical indications for the prostatic urethral lift

The majority of men who are candidates for treatment of LUTS secondary to BPH with the PUL procedure will have suffered from bothersome voiding symptoms for a prolonged period of time and may have developed evidence of bladder wall thickening or trabeculation that can be seen on diagnostic cystoscopy or pelvic ultrasound [17]. Since the treatment of BPH-related LUTS with medications has been codified into various guidelines it is likely that most men will also have taken and failed the standard options of an alpha-adrenergic antagonist or a 5-alpha reductase inhibitor [18]. Therefore, it is expected that the predominant surgical indication for performing a PUL will be bothersome LUTS that have not responded to medical management. There may also be individuals who have suffered intolerable toxicity from medical therapy or who have contemporaneous medical contraindications for such treatment.

(b) UroLift implant comprising capsular tab (CT), polyester monofilament (M), and urethral endpiece (U). *Source:* NeoTract, Inc., California, USA. Reproduced with permission of NeoTract.

Interestingly, the PUL procedure may also be an appropriate choice for men on chronic anticoagulation when this therapy is unable to be safely halted for surgery. Finally, there are likely to be some healthy men with a predictably long life expectancy for whom the palliative treatment with medications provides an inadequate long-term approach to maintaining a healthy bladder.

The preoperative evaluation for a man with bothersome LUTS should be guided by established approaches as outlined in the published guidelines [19]. Although a diagnostic cystoscopy is not required for all men who have elected treatment for LUTS this test can be helpful in determining the optimal candidate for the PUL [20]. A transrectal or suprapubic pelvic ultrasound can also provide useful information about prostatic anatomy, prostate volume and the presence of a middle lobe that could alter the surgical approach [21, 22]. Current selection criteria for men as candidates for the PUL likely mirror, but not exclusively, the inclusion criteria for the L.I.F.T. randomized placebo-controlled clinical trial that resulted in the US Food and Drug Administration (FDA) approval for the UroLift implant device [23]. These criteria included men over the age of 50 with an American Urological Association Symptom Index (AUA-SI) (equivalent to the International Prostate Symptom Score or IPSS) greater than 13 and a maximum urinary flow rate of ≤12 ml/s. In addition, the optimal candidate should have a measured or estimated prostate volume between 30 and 80 $\text{cm}^3$ without a visually obstructing middle lobe.

It is also worth considering other potential indications for performing a PUL in an individual with BPH-related voiding dysfunction. The procedure can be performed under local anesthesia or intravenous sedation making this approach appropriate for medically compromised or frail elderly men who could not otherwise tolerate a bladder outlet surgery. In addition, anecdotal clinical experience has demonstrated that UroLift implants can be deployed safely in men on anticoagulation therapy with only mild hematuria.

Perhaps another common indication is a healthy man who selects the PUL approach in an effort to avoid the risk of sexual dysfunction that has been associated with other bladder outlet procedures. In particular, the creation of an open prostatic urethral channel with the UroLift implants system has been associated with stable or improved erectile function as well as improved ejaculatory function in several clinical investigations [24].

## Surgical technique

The endoscopic technique for PUL is designed to allow the customized placement of each individual implant according to the anatomy of the lateral lobes of the prostate. A cartoon depiction of the surgical approach is provided in Figure 148.2. The spring-loaded needle is of adequate length to perforate through the prostatic parenchyma in an anterior and lateral position to deploy the capsular tab on the external prostatic capsule. The length of the PET monofilament is determined relative to the thickness of the prostatic tissue by compressing the prostatic tissue with the tip of the delivery device. Finally, the inner urethral endpiece is secured to the tensioned monofilament in such a manner that it results in the invagination of the stainless-steel endpiece into the urethral wall. The inert endpiece is rapidly covered by the urothelium within the prostatic urethra, preventing exposure of the device to urine. The specific details of the procedure have been well described by McNicholas et al. in 2013 and will be briefly reviewed again in this chapter [25].

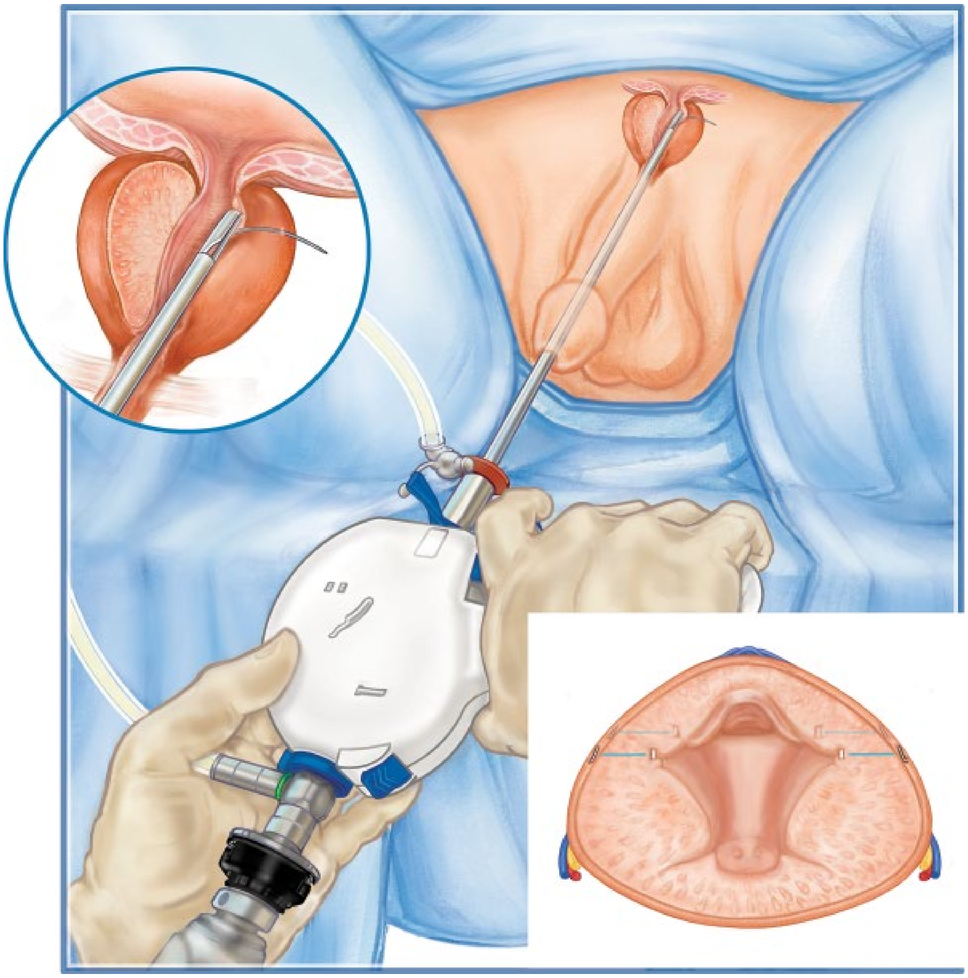

**Figure 148.2** The rigid cystoscope is used to compress the anterior and lateral prostatic parenchyma such that the flexible needle can be extended to deploy the capsular tab and ultimately secure the urethral endpiece. As the figure depicts, the placement of the implants compresses the parenchyma and holds open the prostatic lumen.

The endoscopic technique is performed on an appropriately anesthetized man (either with local lidocaine urethral anesthetic or with intravenous sedation) positioned in the routine dorsal lithotomy position. The most effective anesthetic approach is best determined by the skillset of the treating urologist and the preferences or medical requirements of the patient.

The rigid cystoscope is advanced into the bladder under direct vision using the custom bridge with care taken to avoid urothelial injury that could result in unnecessary bleeding. The care taken in this portion of the surgery can avoid the delays in treatment that would be associated with diminished visualization due to bleeding. The treating urologist will need to evaluate the prostatic anatomy and develop a treatment plan for positioning the individual implants on both sides of the prostate into the anterior and lateral prostatic urethral walls. The endoscopic lens is then placed into the UroLift device, which is subsequently inserted into the rigid cystoscopic sheath and into the bladder. Since the active end of the device protrudes approximately 2 cm beyond the end of the cystoscope, care must be taken to avoid injuring the bladder wall.

The device is then turned 90° to the right or left side and withdrawn into the prostatic urethral lumen. The initial pair of implants is often placed in the proximal urethral lumen approximately 1.5 cm distal to the bladder neck. The device is not activated until the specific location for the implant has been determined. The prostatic tissue is compressed approximately 20° from the midline with the tip of the device. The initial compression may have been positioned at the 9 o'clock location on the right side (or 3 o'clock on the left side) but upward pressure is required to create the anterior lift that will ultimately result in an open anterior channel. Once adequately compressed and lifted, the device is activated and the needle advanced to deploy the capsular tab.

The blue PET suture will be visible within a small window in the tip of the device. The tip of the cystoscope is then advanced slowly toward the bladder, creating a tension on the suture. A white reflection on the blue suture will come into view through the small window once adequate tension has been applied and the luminal endpiece can then be deployed. The device applies the endpiece and cuts the suture simultaneously. This causes the endpiece to visually invaginate into the urethral wall. The implant procedure is then repeated as often as needed to create an open channel from the bladder to the veru montanum. In the L.I.F.T. trial the median number of implants required was 4.9 with a range of 2–11 [23]. Routine clinical practice has resulted in a range of 2–8 implants with the total determined by the individual prostate anatomy.

The procedure is determined as complete when a surveillance cystoscopic examination reveals an open anterior urethral channel without any urethral endpieces visible within the bladder lumen. Any of the endpieces that were inadvertently placed into the bladder lumen at the bladder neck can be easily removed with a flexible grasper. The PET suture will retract into the prostatic parenchyma. The man can then be discharged home either with or without a urethral catheter as consistent with the practice pattern of the treating urologist. The large majority of men will not require a catheter after this surgery.

## Prostatic urethral lift clinical outcomes

Woo and colleagues first reported in 2011 on the technical feasibility and safety of the PUL procedure in men [26]. This preliminary clinical investigation involved 19 men who received the implants under general anesthesia with two versions of the delivery device. All procedures were completed satisfactorily with no serious device- or procedure-related adverse events. Subsequently the delivery device has been standardized as a 20 Fr system and procedures have been performed under all forms of anesthesia including local instillation of lidocaine.

A prospective randomized and sham surgery controlled investigation, called the L.I.F.T. Study, was published in 2013 and provided the foundation for ultimate FDA approval of the UroLift device in the United States [23]. A total of 206 men were randomized to either the sham procedure or the PUL with the UroLift implants using a primary endpoint of comparison of the AUA-SI score at three months. Ultimately, this revealed a reduction in the AUA-SI of 11.1 ± 7.67 points in the PUL group compared to an initial reduction of 5.9 ± 7.66 points in the sham group ($P = 0.003$). A recent publication has compared the clinical outcomes at 2 years in the men who crossed over to the PUL procedure at six months following a sham treatment. In this analysis each man served as his own control and demonstrated a persistent 36% improvement in the AUA-SI from baseline. In addition, other endpoints – quality-of-life score (QOL), BPH Impact Index (BPHII), and maximum urinary flow rate – improved 40%, 54%, and 77% from baseline, respectively [27].

Subsequent to the initial publications there have been a number of prospective clinical trials that have detailed the favorable clinical outcomes of this new procedure [28–30]. Table 148.1 provides an overview of these outcomes.

Although the PUL has demonstrated high-quality outcomes in the context of voiding symptoms it was really the potential to reduce toxicity that was the compelling factor in the development of this new approach. The more established interventions for benign prostatic enlargement include the transurethral resection of the prostate (TURP), various laser-based extirpative approaches and thermal ablative techniques designed to reduce the volume of prostatic tissue that obstructs the bladder outlet. Each of these approaches demonstrates effective reduction of bothersome voiding symptoms but is associated with side-effects that likely cause men to delay or avoid altogether any beneficial therapy. The potential adverse consequences include incomplete resection with the need for repeat interventions, urinary tract infection, urethral stricture, incontinence, and sexual dysfunction. A thorough analysis of the risk for toxicity with each treatment strategy is beyond the intent of this review but several publications may be informative to the interested individual [31–35].

The mechanical principle of the PUL procedure is to endoscopically place a transurethral implant that compresses the prostatic parenchyma to create a more open urethral channel. This can be accomplished with a very favorable toxicity profile when compared to the established extirpative approaches mentioned above. Sonksen and colleagues published a multicenter prospective randomized comparison of the PUL to the TURP in 2015 using a novel composite endpoint measurement called the BPH6. This tool combined measurements of six domains in order to assess overall outcome from each procedure. These domains included LUTS relief, recovery experience, erectile function, ejaculatory function, continence preservation, and safety. A total of 80 men (45 PUL and 35 TURP) were evaluated at 12 months with the PUL found to be noninferior to the TURP [36]. The transurethral resection was superior in achieving a reduction in LUTS but the overall outcome was superior for the PUL. Importantly, there was no statistical difference in the incidence of Clavien–Dindo grade 1, 2, or 3

adverse events between the two approaches. However, urinary incontinence, retrograde ejaculation and urethral stricture were significantly more common in the TURP group. Erectile dysfunction was also more common in the TURP group but the difference did not reach statistical significance.

The information regarding sexual function following a prostate-directed surgery continues to suggest that men consider these risks when making a decision to receive a bladder outlet procedure. Although the risk of erectile dysfunction is small following the extirpative procedures, other sexual dysfunction, such as loss of ejaculatory function, are significantly more common [37]. McVary and investigators for the L.I.F.T. trial reviewed the outcomes for sexual dysfunction using the Sexual Health Inventory for Men (SHIM) and the Male Sexual Health Questionnaire for Ejaculatory Dysfunction (MSHG-EjD) [24]. There was no evidence for a negative effect of the PUL on erectile function. In fact, the 12-month SHIM analysis revealed a statistically significant improvement in erectile function for the men who reported severe erectile dysfunction at baseline. In addition, men reported a 40% reduction in an ejaculatory bother score by the 12 months endpoint of the study. These reports establish the PUL as the only surgical procedure for BPH that can improve ejaculatory function while minimizing any negative effect on erectile function.

Overall, the current clinical experience with the PUL procedure has revealed the technique to be well tolerated with only mild toxicity. Box 148.1 lists the adverse events that were identified during the L.I.F.T. randomized trial. The likely unique adverse event that has been identified with the UroLift implants is encrustation of the urethral endpiece. This was identified during the randomized trial in 2.1% (14 out of 642 total implants). Only those implants with the urethral endpiece inadvertently positioned within the bladder lumen at the bladder neck are at risk for this toxicity. None of the correctly placed devices were found to encrust and the involved endpiece could be easily removed endoscopically with a flexible grasper.

**Box 148.1 Adverse events from L.I.F.T. trial.**

**Serious events**

- Clot retention on coumadin
- Bladder stone (not from implant)

**Related adverse events**

- Dysuria (34%)
- Hematuria (25.7%)
- Pelvic pain (17.9%)
- Urgency (7.1%)
- Urge incontinence (3.6%)
- Urinary tract infection (2.9%)
- Urinary retention (0.7%)
- Erectile dysfunction (0)
- Retrograde ejaculation (0)

## Conclusion

BPH is an obligate condition of the aging man and a source of both QOL and medical health consequences. The development of prostatic enlargement with infravesical obstruction has been shown to alter the structure of the bladder wall and, over time, this alteration likely results in a permanent disorder. A variety of extirpative procedures that remove tissue from the prostate to enlarge the urethral lumen have been found to effectively reduce the bothersome voiding symptoms. These procedures are associated with a risk of adverse events that may cause a man to delay intervention beyond the time at which a complete return to normal bladder health is possible. The PUL procedure with the UroLift implants represents a new mechanical approach for the management of bladder outlet obstruction from prostatic enlargement. A straightforward cystoscopic technique, which can often be performed under minimal anesthesia, allows placement of the implants that compress the prostatic parenchyma and establishes an open channel through the prostatic urethra. This procedure can be performed safely with minimal risk for sexual dysfunction and at an acceptable cost [38, 39].

## Introduction

Benign prostatic hyperplasia (BPH) and its associated lower urinary tract symptoms (LUTS) continue to be a significant burden to healthcare systems around the world. There is an estimated prevalence of histologic BPH of 10% in men in their 30s, with this number rising to 80% in men over the age of 70 years [1]. LUTS due to BPH are associated with significant morbidity and reduced health-related quality of life [2], with the prevalence of moderate-to-severe LUTS increasing with age [3]. An estimated 90% of men aged between 45 and 80 years have some form of LUTS [4].

For the last 80 years, surgical management of the prostatic component of these symptoms has been dominated by the transurethral resection of the prostate (TURP). For many years the only endoscopic option, there is an extensive body of research on the technique, its propensity to improve LUTS, and anticipated adverse events. The TURP is still considered the gold standard in management of the 30–80 ml prostate [5, 6]. The drawbacks of a TURP include the duration of hospital stay, associated adverse events, the long-term sequelae of erectile dysfunction and retrograde ejaculation, blood transfusion rates, and its limitations in high-risk patients.

In recent decades there has been a significant effort to increase the number of techniques available to the urologist to manage LUTS due to BPH [7]. This has been brought about not only by a desire to improve functional outcomes and efficacy, but also in an effort to develop treatments that can be offered to higher risk men, while reducing both morbidity and cost [8]. Such patients include those with larger prostates, increasing age, and those who are anticoagulated or otherwise present a high anesthetic risk.

Laser ablation can be considered as the first alternative to traditional TURP, and was pioneered throughout the 1990s. The neodymium:YAG laser was initially used by Costello et al. [9], with subsequent development of the holmium laser [10] and the 532 nm wavelength, commonly known as GreenLight [11]. Diode and thulium lasers represent newer techniques with a limited numbers of studies, particularly with regard to long-term follow-up [12, 13]. Holmium and GreenLight lasers now appear in both American Urological Association (AUA) and European Urological Association (EAU) guidelines [5, 14] as an effective alternatives to TURP. One of the difficulties in developing new prostatic ablative techniques is that, with surgical options already cited in international guidelines as a gold standard, the urologist must determine how newer techniques compare.

As with any new technique, there are several areas that must be examined in order to determine whether it can be considered as an alternative to an already established treatment. In the treatment of BPH, these include both short- and long-term efficacy, patients' ability to tolerate treatment, potential complications, impact on quality of life (QOL), and economic costs [15].

Ablative techniques currently in use include laser, thermoablation, radiofrequency ablation, aquablation, and injection of ethanol. Although some of these techniques are now approaching 30 years in clinical use, others are much more recent, meaning that only short-term outcomes are available. A lack of high-quality randomized controlled trials and limited head-to-head data, means that the majority of trials are set up to demonstrate noninferiority to another treatment, usually TURP. Whether these newer treatments represent equivalence to established techniques must therefore be based on similar outcome data, with long-term outcomes inferred.

The LUTS associated with BPH have been found to affect how men organize their day, and may prevent them from performing their preferred daily activities [16]. The primary goal of any therapy should therefore be relief of symptoms and prevention of long-term adverse outcomes that will adversely affect QOL. Accepted methods of measuring outcomes in the treatment of LUTS due to BPH include the use of uroflowmetry, postvoid residual (PVR), urodynamics, AUA Symptom Index (AUA-SI) or International Prostate Symptom Score (IPSS), incontinence, sexual function outcomes as assessed by the International Index of Erectile Function (IIEF), and the need for further procedures.

The 2010 AUA guidelines [14] define three important outcome measures when considering therapies for BPH: (i) a comparison of the efficacy of available treatments; (ii) treatment-associated adverse events; and (iii) identification of subpopulations in which efficacy and adverse events differ from the general population. In developing these guidelines the panel used symptom and QOL scores (primarily AUA-SI/IPSS) and peak urinary flow ($Q_{\max}$) to assess efficacy. These outcome measures should therefore be considered as a minimum in the assessment of newer therapies. Comparison of adverse events (AEs) is more difficult, primarily due to the heterogeneity among trials in how AEs are reported. Many newer therapies seek to take advantage of the subpopulations that may benefit from alternative treatment methods, particularly the elderly or those at high risk from anesthesia.

Uroflowmetry, originally developed from research into pressure-flow studies, as a means of indirectly evaluating the presence of obstruction [17], is an important component of the assessment of many BPH interventions. The majority of studies therefore use the uroflow as an outcome measure of the success of a given intervention. The most commonly used value in clinic practice is the $Q_{\max}$, but unfortunately this correlates poorly with subjective symptoms and the degree of bother experienced by the patient. Despite this limitation, it provides an excellent means of comparing functional outcomes between treatment groups.

The AUA-SI was developed in the early 1990s as a standardized instrument to assess the degree of bladder outflow obstruction in men [18]. This was further modified to develop the IPSS with the addition to the original of a "bother" score, as a QOL measure [19]. Symptom scores are stratified with a score <7 being mild symptoms, score 8–19 moderate, and 20–25 severe. Both of these scoring systems have been extensively validated and are sensitive enough to be used in the evaluation of symptoms and to assist in selection of treatment [20–22].

One of the most important things to note regarding the IPSS system is the frequent discrepancy between symptom severity and QOL scores [23]. A significantly improved symptom score may represent treatment success, but if there is ongoing reduced QOL then the patient may continue to be dissatisfied and seek medical attention. The Veterans Affairs Cooperative Study showed that the significant factor predicting elective crossover from watchful waiting to TURP was high baseline bother due to urinary symptoms, with outcomes better in men most bothered by urinary symptoms at baseline [24]. It is therefore important to consider both these scores in the success or failure of new therapies.

Complications such as failure to void, recatheterization, symptoms of dysuria and frequency, and need for reoperation represent a significant burden for both the patient (QOL and satisfaction outcomes) and healthcare systems (the cost of repeat hospital attendances and interventions). TURP has a well-documented range of complications, as follows: failed trial removal of catheter (TROC) (6%), transfusion (1–4%), clot retention (3%), infection (2%), contracture/stricture (6%), transurethral resection syndrome (2%), incontinence (1%), and erectile dysfunction (13%) [25–28]. Newer techniques should provide comparable or improved complication profiles in order to be considered competitive.

One of the appeals of several of the newer treatment modalities is that they can be effectively used in higher risk patients who might otherwise be considered unsuitable for a traditional TURP. The ability to perform ablation procedures on anticoagulated patients without significant complications, or the fact that a technique can be performed in the outpatient setting might make it competitive compared to established techniques.

In order to capture long-term outcomes it appears that a median of at least 3 years of data in a large number of men are required [29], and for many newer therapies the data are simply not mature enough to allow this. Long-term efficacy is important in order to assess the economical viability of newer therapies, with low retreatment rates important. Although early results may be promising, it is clear that longer follow-up is required for many ablative techniques.

The true economic cost of BPH treatment is multifactorial, involving not only the cost of drugs, imaging, clinic and hospital attendances, equipment and staffing, as well as the actual procedures, but also the repercussions of lost earnings and time off work. It has been estimated that in the United States the treatment of BPH costs approximately US$4 billion annually [30]. A recent study reveals that 12.2 million BPH patients are treated each year, with 55% being treated with medication and 1% treated surgically [31]. It is expected that, with an aging population, the economic cost of treating BPH will only increase.

There is an ever-increasing range of surgical therapies available for the management of BPH, many of which have only short-term follow-up data available in order to assess outcomes. Here we outline some of the more recently developed techniques that have been used in the treatment of LUTS due to BPH.

## Transurethral microwave therapy

Transurethral microwave therapy (TUMT) involves the placement of an intra-urethral antenna to facilitate heating of the prostate to temperatures above 45 °C, causing tissue destruction by coagulation necrosis. Although this technique has been found to improve both IPSS, which decreased by 65% over 12 months, and $Q_{max}$, which improved by 70%, neither of these results were as good as TURP, with a 77% decrease and 119% increase, respectively [32]. A single randomized controlled trial (RCT) compared TUMT to medical therapy with terazosin, rather than surgical techniques, with significantly better outcomes in the TUMT group over 18 months follow-up.

TUMT has been shown to be successful in the management of patients in urinary retention, with 80–93% of patients regaining spontaneous voiding after treatment [33, 34]. The majority of this follow-up data are, however, in the order of less than 12 months and one study suggests that there is a cumulative risk of treatment failure in this subgroup of patients in the order of 59% at 5 years [35].

The majority of AEs related to this technique involve perineal pain, dysuria and urgency, with few of the more significant morbidities associated with TURP. In particular, sexual dysfunction and urethral stricture rates have been found to be lower. The technique cannot, however, be used in patients with a middle lobe or short prostatic urethra. In favor of TUMT is the fact that there is no requirement for general anesthesia, making it appealing in those patients with significant comorbidities or anesthetic risk. It is, however, important to bear in mind the trade-off in terms of lower flow improvements and higher retreatment rates when compared to TURP.

## Transurethral needle ablation

Transurethral needle ablation (TUNA) involves cystoscopic insertion of needles into prostatic parenchyma under direct vision. Low-level radiofrequency energy is then transmitted down these needles, causing coagulation necrosis in the transition zone. A meta-analysis of 35 studies [36] has demonstrated a significant improvement in both IPSS and $Q_{max}$, in the order of a 50% decrease in symptom score and 70% improvement in flow, but as with TUMT these outcomes are significantly inferior to TURP. At 5 years of follow-up in a single study, approximately 50% of patients had maintained their improved outcomes, but there was a 21% additional treatment rate [37].

The most common adverse event of TUNA is that of postoperative urinary retention, which occurs in 13–42% of patients. 90–95% of patients are catheter free within a week, but storage LUTS are common for 4–6 weeks following treatment [38, 39]. This method cannot be used in patients with a prostate size greater than 75 ml, nor is it suitable in those with a middle lobe. It can, however, be performed as a day case, and has a lower rate of bleeding and sexual dysfunction when compared to TURP. The 5-year retreatment rates are high, and do raise concerns about the durability of this technique when compared to others that are available.

## Prostate stents

A variety of stents have been trialed, differing in design and materials and whether they are permanent or not. The majority of studies have high dropout rates, almost certainly related to poor tolerability due to migration, misplacement, encrustation, and subsequent exacerbation of LUTS [40]. UroLume, a permanent stent, enabled 84% of catheter-dependent patients to regain their ability to void, but also reported a failure rate of 16% at 12 months, increasing to 27% at 5 years [41]. It is no longer commercially available.

Various temporary blind-placement stents have also been trialed, but have been found to have significant side-effects and a high migration rate, leading to the conclusion that they are unsuitable for clinical use [42, 43]. The Memokath system, a self-expanding, removable metallic stent has also been used in this setting. Results are more favorable here, with a reduction in IPSS of 11–19 points and increase in $Q_{max}$ of 3–11 ml/s [44]. Current EAU guidelines suggest that prostate stents should only be considered in men unfit for surgery or as a temporary measure [5].

## Intraprostatic ethanol injections

Ethanol is injected directly into the prostatic parenchyma using either a transurethral, transperineal, or transrectal approach. Studies have used anything between 2 and 25 ml of ethanol at a variable number of injection sites. Most patients require catheterization following the procedure. Several nonrandomized open trials report a significant reduction in IPSS of 40–70% and $Q_{\max}$ improvement of 35–155% [45, 46].

Again there are concerns about the durability of treatment, with a single trial reporting a 41% retreatment rate at 3 years [47]. In addition to pain, storage LUTS, hematuria, retention, and infection, two cases of bladder necrosis were reported [48]. Both patients required cystectomy and urinary diversion. The lack of evidence and severity of AEs has meant that intraprostatic ethanol injections are regarded as unsuitable for use outside clinical trials.

## Intraprostatic botox injections

Botulinum toxin A is injected into the prostatic parenchyma using the transperineal, transurethral, or transrectal route. The drug induces apoptosis in epithelial cells, leading to tissue atrophy and neuronal inhibition, which may contribute to smooth muscle relaxation. A variety of different doses have been used. A single review of 20 studies [49] demonstrates significant IPSS reduction in 13 studies, $Q_{\max}$ improvement in 14 studies, and durability ranging from 3 to 30 months. The largest placebo-controlled study [50] did not, however, show any significant difference in any parameter at 12 weeks posttreatment. At this stage the lack of evidence that botulinum toxin is effective in this situation, coupled with a paucity of controlled trials, means that intraprostatic botulinum toxin is still considered experimental.

## Aquablation

This technique uses a high-velocity saline stream to resect parenchymal tissue, with subsequent hemostasis achieved using brief thermal coagulation. The AquaBeam® system (Procept BioRobotics, Redwood Shores, CA, USA), combining real-time transrectal ultrasound imaging and robotics, has been through phase I and II studies, and a large multicenter RCT is ongoing [51]. Initial trials show significantly improved functional parameters with an IPSS decrease of 63–90% and $Q_{\max}$ increase of 54–101% [52–54].

Reported complications have been minor and included dysuria, retention, mild hematuria, and infection. Sexual function and continence have been preserved with no reports of significant AEs. The technique is still in its early stages with long-term data lacking.

## Water vapor energy ablation

The Rezūm® system (Rezūm Water Vapor Therapy, Maple Grove, MN, USA) injects water vapor at 103 °C via a transurethral approach into the transition zone and median lobe as needed, causing thermal ablation. The number of injections is determined by the size of adenoma and length of prostatic urethra. Results from a multicenter RCT [55] show significant improvement in IPSS of 53% and $Q_{\max}$ of 54% at 12 months.

The procedure appears to be well tolerated and is performed in the outpatient setting. AEs include retention, dysuria, hematuria, and infection, with no serious complications reported. Again, long-term data are lacking, but results appear durable over at least 12 months.

# Monopolar Transurethral Resection of Prostate

*Madhu S. Agrawal & Dilip K. Mishra*

*Department of Urology & Center for Minimally Invasive Endourology, Global Rainbow Healthcare, Agra, India*

## Introduction

Transurethral resection of the prostate (TURP) has been the gold standard in surgical management of patients with benign prostatic hyperplasia (BPH). The procedure has stood the test of time while many new, alternative “minimally invasive” procedures have failed to last in an era of procedure avidity. The place of conventional TURP using monopolar energy has recently come under scrutiny with the emergence of bipolar electrosurgical systems, which have become increasingly popular. The underlying principles of both monopolar and bipolar electrosurgical systems are similar, but the manner in which the current returns to the generator is different. However, owing to its widespread availability and use, monopolar TURP will continue to be an important tool in the therapeutic armamentarium of urologists dealing with BPH patients.

## History

Electrosurgery had its beginning in 1882 when d’Arsonval found that high-frequency alternating current, when passed through the body, caused heating without muscle and nerve stimulation [1]. Young (1909) improved the endoscopic application of electrosurgery by using a fenestrated tube in place of an inner cutting tubular knife for the cold punch operation for prostatectomy [2]. This innovation allowed water to be infused between the electrode and the sheath, thereby improving vision and cooling the instrument. Edwin Beer (1910) is credited with being the first to make use of electrosurgery endoscopically by placing an electrode through a Nitze cystoscope to remove tumors of the bladder neck [3]. Stevens and Bugbee performed the first electrosurgical endoscopic incision of the prostate in 1913 [4, 5].

The development of the spark gap generator was a landmark invention which came into existence with the pioneering efforts of Liebel and Bovie in 1924 [6]. This generator was able to produce both cutting and coagulating waveforms, which greatly facilitated hemostasis while resecting the prostate. Shortly after this invention, Stern developed the early resectoscope using a cutting loop consisting of a small ring of tungsten wire of approximately 0.5 cm in diameter [7]. The loop was placed at right angles to the end of an insulated shaft and was connected such that the loop could be made to slide easily. The radiofrequency current was then delivered continuously under water to excise prostate tissue. However, securing hemostasis was still an important issue. Davis, by using the Bovie generator, not only overcame this problem, but also became the first to use it for excision of large amounts of prostate tissue. Joseph McCarthy in 1932 subsequently developed the McCarthy resectoscope, which bears significant resemblance to the modern resectoscopes. The invention of rod–lens optical systems by Harold H. Hopkins in 1959 and the addition of fiber-optic light transmission by Karl Storz in 1960 marked further breakthroughs in modern endoscopy [8]. Since then, several refinements in instruments and technique have been made by outstanding urologists, but the basic principles have remained the same.

## Electrosurgical basis of transurethral resection of the prostate

The entire concept of TURP (monopolar or bipolar) is based on the principles of electrosurgery. Ablation of the prostate is achieved by employing alternating current with wavelengths in the radiofrequency range. The standard alternating current, with frequencies in the 60 Hz range, is unsafe for use in this setting as it subjects

the patient to the risk of excessive neuromuscular stimulation, leading to tonic–clonic contractions with rhabdomyolysis and cardiac arrhythmias. The role of an electrosurgical generator is to increase the frequency of this current to over 200 kHz, because at all frequencies above 100 kHz current can pass through the body with minimal neuromuscular stimulation and no risk of electrocution.

While using a monopolar system for TURP, the active electrode (cutting loop) is placed in contact with the prostate tissue. Inside the resectoscope, the electrical connection from the generator to the cutting loop is carefully insulated. When activated, the generator produces a high-frequency voltage which drives a high-frequency current through the patient. The current passes from the small active electrode (cutting loop) at the tissue interface, through the patient to a proportionately larger indifferent electrode, and subsequently back to the generator (Figure 150.1). Thus, in a monopolar TURP, the patient is part of the system. Alterations in the frequency of oscillation and waveform alter the quality of coagulation and cutting.

The current flowing through the patient heats the tissue in contact with the loop, the heat generated being proportional to the current density (current flowing per unit area). The current density is high only in the tissue neighboring the current loop, leading to vaporization of the fluid in the cells near the loop, which can be moved through the tissue almost without any mechanical force.

## Types of current waveforms

The basic function of an electrosurgical unit is to fulgurate or coagulate tissue by use of low-frequency current and the incision of tissue with high-frequency current. Depending on the characteristics of the generator, a variety of current waveforms can be produced (Figure 150.2). The individual settings are governed by the machine and requirements of the surgical procedure. The historical terms “coagulation” and “cutting” waveforms can be misleading as low-power settings in the cut mode produce excellent contact coagulation, while high-power settings in the coagulation mode will produce a cutting action.

### Cutting waveform

Cutting current uses a pure, nonmodulated sinusoidal waveform. Electrosurgical cutting requires the generation of small arcs from the electrode to the tissue, which occur twice during each cycle at the maximum and minimum voltage of the sine wave. This implies that the frequency of these arcs will be double the frequency of the sine waves produced by the generator, thereby facilitating a smooth cutting action without extensive thermal damage. This waveform achieves a higher average power when compared with any other alternating waveform of equal peak voltage (>500 V), allowing the voltage to be limited when compared with coagulation current. It is important to remember that the described cutting effect depends only on the magnitude of the current density,

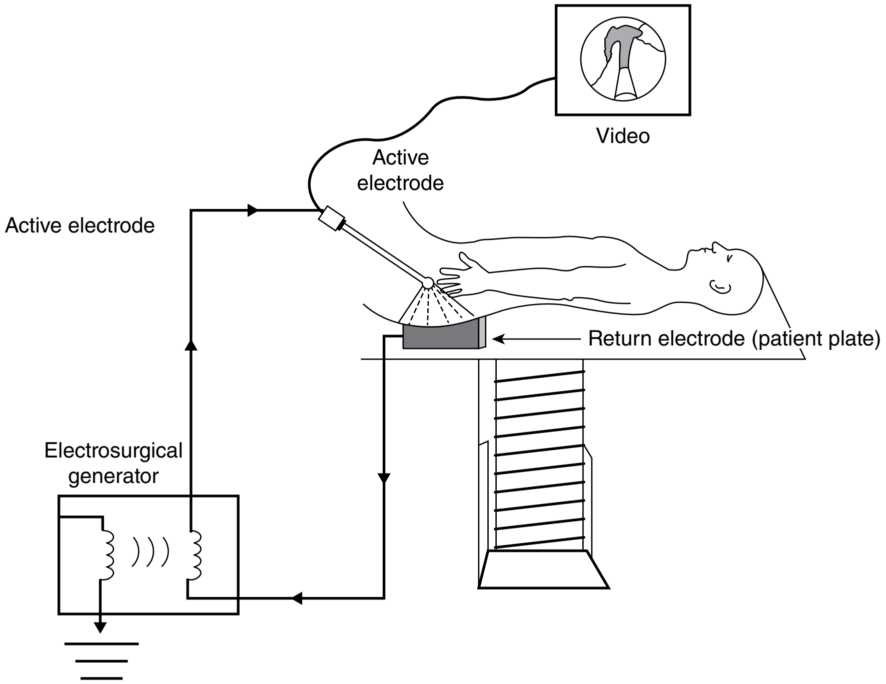

**Figure 150.1** Monopolar circuit.

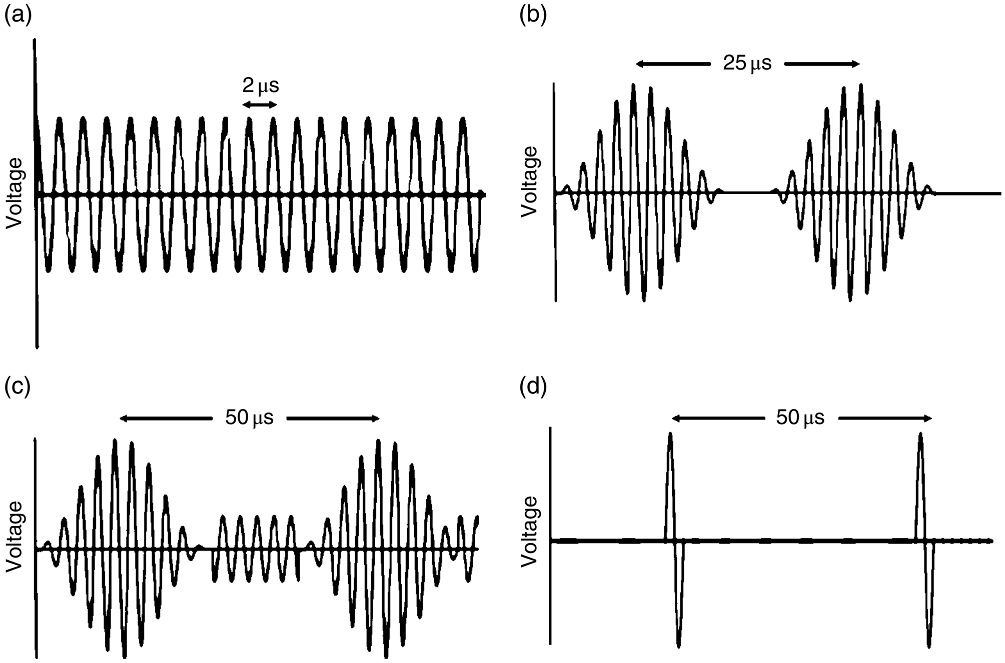

**Figure 150.2** Waveforms. (a) Cutting current; (b) coagulating current; (c) blended current; (d) spray coagulation.

not on the frequency of the current. In general, cutting is produced by high tissue temperatures (>100 °C), whereas coagulation is produced by tissue heating between 70 °C and 100 °C.

While performing TURP, a higher setting for the cutting current increases greatly the efficiency of the cut, while adding little to the danger of the procedure. On the other hand, too much cutting current produces a noticeable blue flame between the electrode and the tissue, which should be avoided. In general, small fibrous glands or bladder neck contractures are best treated by using a small-caliber loop with a high-intensity cutting current.

## Coagulation waveform

Coagulation current is a highly dampened current characterized by extensive wave modulation in which the generator supplies current for less than 50% of the activation time. This produces intermittent bursts of damped sine waves of high peak voltages, up to 10 000 V (Figure 150.2b). When employed, with the active electrode in contact with the tissue, these peak voltages result in high tissue temperatures, and hence significant thermal destruction, making this type of current particularly suited for the coagulation of bleeding vessels. Therefore, when this type of current is used in TURP, the intensity should be as low as will reasonably coagulate the tissue, and the time of application should be as short as possible.

## Blended waveform

Blended currents are actually a combination of the above two waveforms, created by modulating a second, lower frequency, higher amplitude sine wave with the sine wave from the cutting generator, producing a higher peak-to-peak voltage. This waveform typically supplies current for only 50–80% of the activation period. The new waveform is then delivered in intermittent bursts at a rate determined by the settings of the electrosurgical generator. Blended currents allow the surgeon to cleanly divide tissue while maintaining a variable degree of hemostasis, depending on the amount of coagulating current used. Because more vascular glands have higher moisture content, this type of tissue is best resected using a blended current to maximize cutting and coagulation properties.

## Spray coagulation waveform

This waveform is highly intermittent, with the generator supplying current for only 5% of the activation time. It is also high voltage (up to 10 kV) to produce long sparks between electrode and tissue. Operating in this mode, the active electrode does not touch the tissue, but instead, the high voltage causes air ionization and sparking. This mode uses relatively low current output (approximately 0.1 A) and thus leads to a thin layer of tissue necrosis with little depth of thermal damage.

## Irrigation fluids

A hypo-osmolar irrigation fluid (1.5% glycine) is used that is nonconducting and not too rapidly absorbed. Despite having an osmolality of 200 mOsm/kg, it has played a role in reducing the risk of hemolysis and death by more than 50% from the days when distilled water was used for irrigation [9]. A variety of other electrically nonconducting irrigation fluids such as 5% dextrose, 3% mannitol, and 3% sorbitol have also been used. Normal saline is not suitable for monopolar TURP as it may prevent the creation of a cutting arc because of its conductivity.

## Indications for transurethral resection of the prostate

In 1989, the American Urological Association (AUA) initiated the Guideline Panel for Diagnosis and Management of BPH, which was later taken over by the Agency for Health Care Policy and Research (AHCPR) [10]. The panel subsequently recommended the AUA-7 Symptom Index for formal assessment of a patient's symptoms. The current indications for performing TURP are listed in Box 150.1.

**Box 150.1 Current indications for transurethral resection of the prostate.**

- Moderate (8–19) to severe (20–35) lower urinary tract symptoms (LUTS) not responding to medical treatment
- Refractory urinary retention with at least one failed attempt at catheter removal
- Chronic retention with back pressure changes, leading to:
  - Hydronephrosis
  - Renal insufficiency
- Complications of benign prostatic hyperplasia (BPH), including:
  - Recurrent urinary tract infection
  - Recurrent gross hematuria
  - Bladder diverticula
  - Bladder stones

## Preoperative evaluation

### Patient assessment

As most patients undergoing TURP are elderly, assessment of the renal, cardiac, pulmonary, and general physiologic status is of paramount importance because major derangements in these vital organs are important predictors of postoperative outcome. In addition to routine blood investigations, including hemoglobin, complete and differential blood counts, blood sugar, prothrombin time, and partial thromboplastin time. Renal function tests (including serum creatinine and blood urea nitrogen) should be obtained, and surgery should be postponed and catheter drainage done in patients with impaired renal function due to obstructive uropathy. Such an approach allows maximum possible improvement in renal function before the patient is taken up for surgery. An ultrasound abdomen with special emphasis on the kidney, ureter, and bladder (KUB) region should be obtained to assess the prostate size and postvoid residual volume (PVR). In patients who have not been catheterized, uroflowmetry is considered the single best noninvasive test to detect lower urinary tract obstruction. Pressure flow studies should only be done when the diagnosis is unclear or neurological disorder is suspected. A prior cystoscopic assessment is generally not necessary and it can be done at the time of the procedure.

## Perioperative antibiotics

Patients with evidence of infection should be treated prior to the planned procedure. Although the impact of prophylactic antibiotics in reducing postoperative infection was refuted by some authors, most of the available literature supports their beneficial role [11–16]. The antibiotic should cover both Gram-positive and Gram-negative organisms. Patients with an indwelling catheter are at a higher risk, even if no preoperative evidence of infection is detected. It is our practice to routinely administer a single intravenous dose of a broad-spectrum prophylactic antimicrobial 1 hour before the procedure. The patient is subsequently continued on oral antibiotics until they are catheter free.

## Anesthesia

The choice of anesthetic should be individualized, and the procedure can be performed under spinal epidural or general anesthesia with similar results [17–19]. Small-volume glands (<40 g) can also be resected under local anesthesia, especially when associated major comorbidities are present [20, 21].

## Surgical technique

The patient is placed in the modified lithotomy position. Care is taken to avoid overextension at the hip joint, and adequate padding is used for bony prominences.

Cystourethroscopy is done as the first step to assess the distal urethra, position of verumontanum, size and

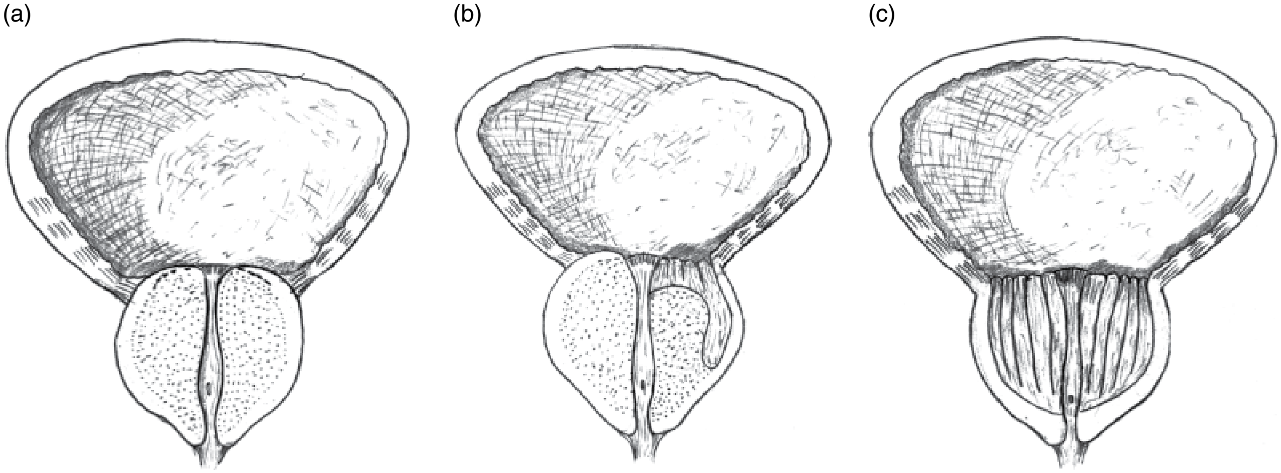

**Figure 150.3** Stages of transurethral resection of the prostate: coronal representation.

configuration of the prostate, bladder neck, urinary bladder, and both ureteric orifices. In case of urethral narrowing, urethral dilators are used to dilate it to 28 Fr. Sometimes internal urethrotomy may be required to accomplish this. Meatal dilatation or dorsal meatotomy is done if the meatus is narrow.

The resection technique may vary according to the size or configuration of the prostate, but should be based on an orderly plan. There are several different surgical techniques described for TURP adenoma; however, the principle remains the same, (i.e. step-by-step resection and coagulation of each quadrant of prostatic lobes) (Figures 150.3 and 150.4). The operator is expected to get familiar with any one approach, and then to master it with experience. A commonly used approach, popularized by Nesbit, utilizes the principle of resecting anteriorly first so that the adenomatous tissue drops down, allowing the surgeon to resect from the top downwards rather than from the floor upwards.

A 24 or 26 Fr size resectoscope, the continuous irrigation variety (Iglesias), is the most commonly employed equipment. The resectoscope is placed at the level of the verumontanum and the adenoma is resected in quadrants. Resection begins at 12 o'clock at the bladder neck, and is then carried down anticlockwise to the 9 o'clock position in a stepwise fashion to a depth where circular fibers of the bladder neck become visible. The resection is carried down to the surgical capsule, which is recognized as a rather fibrous structure compared with the granular appearance of the prostatic adenoma. The other anterior quadrant, from 12 to 3 o'clock, is next resected clockwise.

Resection of the anterior quadrants results in the lateral lobes falling toward the floor. Resection of right lateral lobe is started at approximately the 9 o'clock position and continued in an anticlockwise fashion. The resection is carried to the right side of the verumontanum. For the left lobe, a similar procedure is started at approximately 3 o'clock and carried clockwise to the left side of the verumontanum. After completion of the lateral lobes, the tissue at 6 o'clock, including the median lobe if present, can then be resected up to the verumontanum. Care must be taken not to resect too deeply in the region of the posterior aspect of the vesical neck to prevent undermining of the trigone.

Large adenomas can be resected using "encirclement," a modification of the above-mentioned technique. During resection of the lateral lobes, a groove is created between the bulk of adenoma tissue and the surgical capsule by working the resectoscope loop along the capsule, allowing the lobe to fall to the floor. The loop works somewhat like the finger of the operating surgeon in the open transvesical prostatectomy, separating the lobe from the surgical capsule of prostate. The procedure is done first on one side and then on the other side. Finally, the remaining bulk of tissue on the floor, which by now is mostly devascularized, can be resected quickly to complete the procedure.

Another variation of the technique, popularized by Blandy, starts with resection of the floor at the 6 o'clock position, including the median lobe if present. This is followed by resection of each lateral lobe from the 12 o'clock down to the 6 o'clock position in the standard fashion. The advantage of this approach is to establish the tissue planes and landmarks at the beginning of the operation. This approach can be especially useful in prostates with a large median lobe.

Toward the end, the apical portion of the lobe remains; this is resected last. Care must be taken to avoid extending the resection beyond the level of verumontanum to protect the external sphincter mechanism, which lies just distal to it. The most common area of damage to the external sphincter is at the 12 o'clock position. Thus, care must

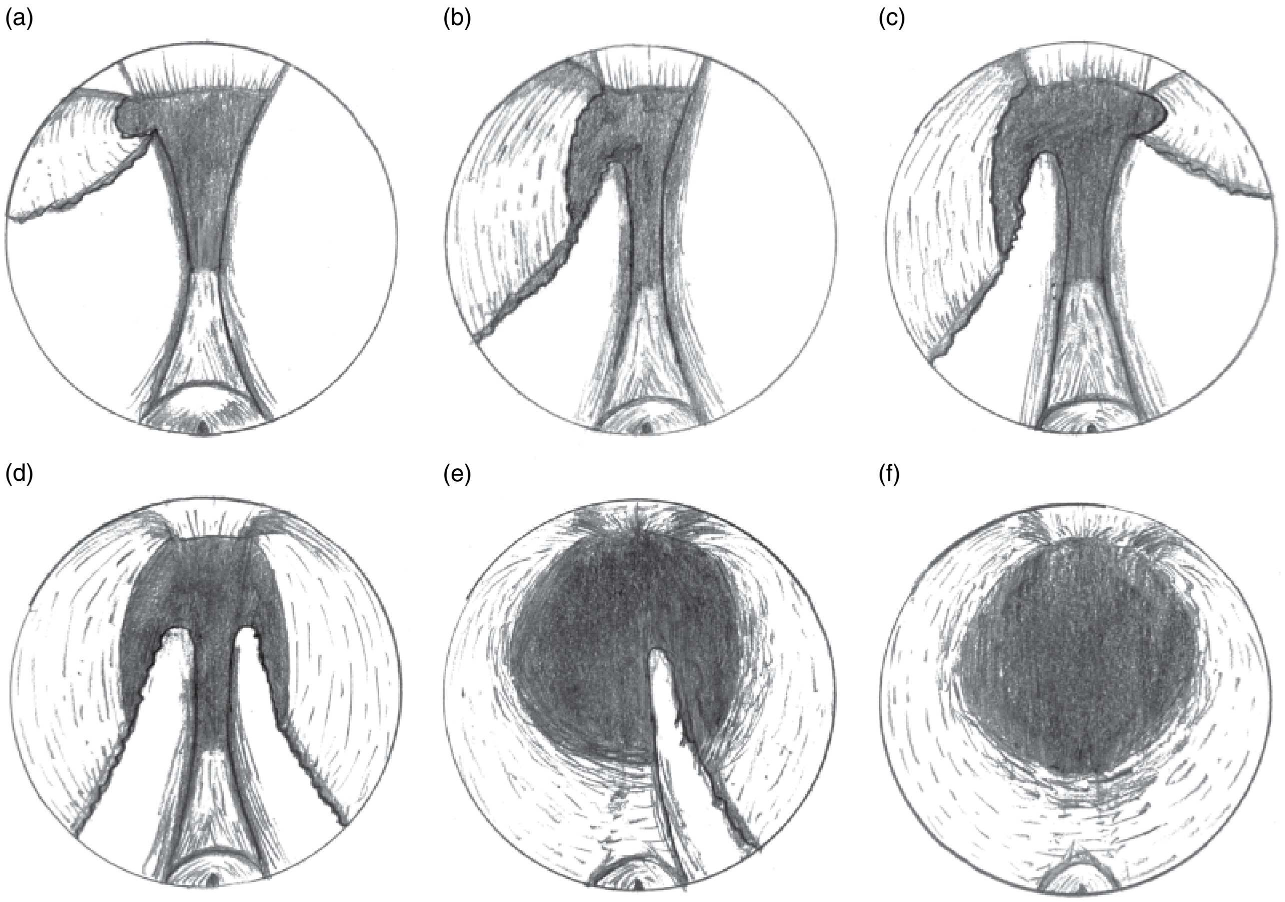

**Figure 150.4** Stages of transurethral resection of the prostate: endoscopic view.

be taken as the 12 o'clock position is approached. The resection, especially the apical portion, may be performed with a finger in the rectum, for which a rectal shield can be put in place at the beginning of the operation. When the resection is completed, the resectoscope is pulled just distal to the verumontanum, to see that there is no falling or obstructing tissue. Any remaining adenoma tissue can be judiciously trimmed down to the surgical capsule, taking care not to damage the sphincter mechanism.

Hemostasis is of prime importance, and must be maintained meticulously throughout the operation. The arterial bleeders are best coagulated at the level of the surgical capsule using spray coagulation. Complete hemostasis must be achieved at each stage, before resection proceeds to the other quadrant.

## "Hemiresection" of the prostate

TURP for large glands may be associated with significant morbidity, mainly due to absorption of irrigant and blood loss. When extensive resection of the prostate tissue is carried out, opening of venous sinuses can be associated with troublesome bleeding and/or excessive absorption of fluid, resulting in "TUR syndrome."

Similarly, in medically compromised elderly individuals (cardiomyopathy, ischemic heart disease, chronic obstructive respiratory disease, renal insufficiency, etc.) standard TURP may carry greater risk. In such patients the procedure may sometimes need to be terminated prematurely due to blood loss and/or excessive fluid absorption, because of the prolonged operating time.

However, incomplete resection leads to a large raw surface. Good hemostasis is not achieved because of the retraction of the blood vessels within the adenoma, leading to a greater incidence of hemorrhage and infection. In addition, incomplete resection of the prostate leads to poor flow rates postoperatively, and recurrent retention due to the "falling in" of the residual adenoma. It is also associated with a higher complication rate of reactionary and secondary hemorrhage, persistent postoperative urinary infection, and early recurrence [22].

In such a situation, an alternative solution is termination of the procedure after "complete" resection of one

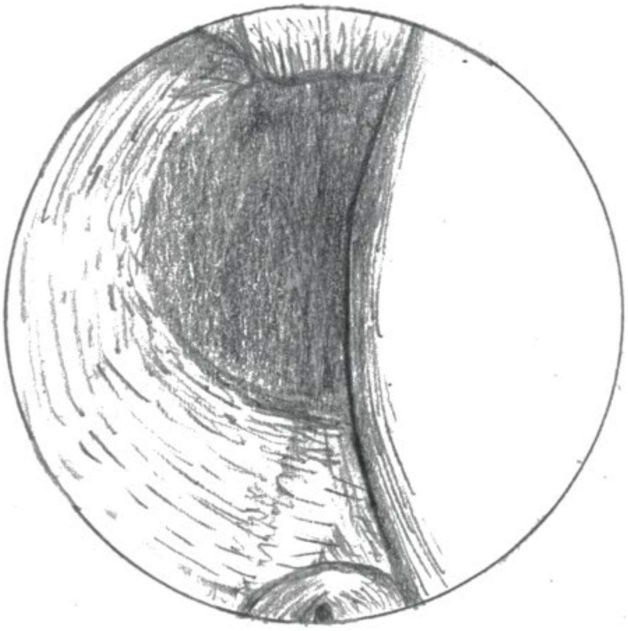

**Figure 150.5** "Hemiresection": endoscopic view.

lateral lobe (and the median lobe, if present) of the prostate. This procedure, termed "hemiresection" of the prostate (Figure 150.5), allows completion of the procedure quickly to avoid complications of excessive blood loss and/or fluid absorption, while at the same time avoids the problems associated with "incomplete" resection.

The patients undergoing hemiresection have the advantage of shorter operating time and less blood loss compared to those undergoing standard TURP. At the same time, complete resection of one lateral lobe (and the median lobe if present) prevents the complications of hemorrhage and persistent infection associated with incomplete resection, and ensures a good channel for adequate flow. The other lateral lobe that is left untouched remains attached to the surgical capsule of prostate and therefore does not "fall in" to obstruct the channel and increase the incidence of postoperative retention of urine. In addition, there is no raw area of incomplete resection as the mucosa over the unresected lobe remains intact.

In a prospective randomized trial at our center in a series of 163 patients, the results of standard TURP and prostatic hemiresection were found to be comparable in terms of reduction of PVR, improvement in symptom score, and peak flow rate [23]. No patient developed retention of urine in the postoperative period. The incidences of blood loss and TUR syndrome were lower in the hemiresection group.

Prostatic "hemiresection" allows early termination of TURP in case of need, to avoid complications of excessive blood loss and fluid absorption. At the same time, it avoids the problems associated with "incomplete" resection. "Hemiresection" or "hemi-TUR" may be considered an acceptable option if the surgeon gets into trouble in the middle of an operation, or even as an elective operation in men with large glands and severe medical comorbidity, without compromising the basic principles of TUR surgery.

## Postoperative care

Most urologists prefer to apply traction on the irrigation catheter for a period of 2–6 hours. Continuous irrigation is provided with prewarmed fluids, with care taken to ensure proper outflow. The early postoperative period requires careful monitoring for prompt recognition of any complications. It is desirable to have an assessment of hemoglobin and electrolytes in this period. Patients are made to ambulate after traction is removed. Antimicrobials are continued until the patient is catheter free (i.e. 3–5 days).

## Outcomes

The AHCPR panel conducted a meta-analysis of various clinical studies and found the results of TURP to be significantly better in comparison to other less invasive procedures [24]. TURP improved symptoms in 70–96% of patients (mean 85%).

The mortality rates following TURP have shown a significant decline since the introduction of the procedure. The current mortality rates range from 0% to 0.25% [25]. This reduction indicates that progress has been made in making the procedure safer than it originally was. Technologic advances, such as microprocessor-controlled units, better armamentarium such as video TURP, and better training have contributed to this improvement.

## Complications

### Early complications

**Hemorrhage**

Hemorrhage is the most frequent complication. Larger glands and resection times of longer than 90 minutes are associated with a higher incidence of bleeding. The bleed can be arterial or venous and complicates both intraoperative and postoperative management. Arterial bleeding should be suspected if the irrigation catheter shows continuous passage of bright red blood. As a general principle, during resection all bleeding from an area of the prostatic fossa should be controlled using coagulation before moving to another area. Venous bleeding is darker and generally occurs after a period of initial clear irrigant in the postoperative period. Reapplication of traction on the catheter with or without overinflation of the balloon can be useful in these cases. Excessive bleeding, especially if suspected to be arterial, may require repeat cystoscopy with electrosurgical coagulation to control the bleeding.

#### Resection errors

Over-resection with perforation of the prostatic capsule leads to extravasation of irrigant. It is characterized by restlessness, vomiting, and abdominal pain localized to the lower abdomen and back (a noticeable feature in a patient who has undergone spinal anesthesia). Immediate termination of the procedure with control of bleeding is of paramount importance in these patients. Most patients respond well to a period of catheter drainage and antibiotics.

#### TUR syndrome

This complex syndrome of fluid overload, dilutional hyponatremia, and hemolysis due to systemic absorption of large amounts of irrigant, especially in patients with a gland size larger than 45 g and a resection time of more than 90 minutes. Mebust et al. observed that TUR syndrome occurred in 2% of patients [10]. The syndrome may occur as quickly as 15 minutes after the resection starts or up to 24 hours postoperatively [26–29]. It is characterized by confusion, nausea, vomiting, hypertension, bradycardia, and visual disturbances. Monitoring the serum sodium concentration is important as the syndrome does not occur until the serum sodium falls below 125 mEq/dl. Intravenous hypertonic saline, diuretics, and termination of the procedure may be required when this happens. Madsen and Naber observed that limiting the height of the irrigation bottle to 60 cm above the prostate reduced the intravascular fluid absorption [30]. Leaving a rim of tissue on the capsule until the end of the procedure, where it can be left if signs of TUR syndrome are evident, may reduce the risk of absorption due to opening of prostatic sinuses [31, 32].

#### Obturator nerve stimulation

Most instances of obturator nerve stimulation occur following transurethral resection of bladder tumors and TURP is very infrequently implicated. When it occurs, stimulation of the obturator nerve produces a sudden thigh movement that can cause the cutting loop to bite more deeply, and often at an undesired location. Various modalities have been tried to prevent adductor spasm during spinal anesthesia, ranging from local blockade of the obturator nerve, periprostatic and subvesical lignocaine infiltration, changing the site of the inactive electrode, reduction of the electrocoagulation voltage, and general anesthesia with muscle relaxants. However, local blockade of the obturator nerve seems to be the most effective in preventing this complication [33–35].

#### Intraoperative priapism

Intraoperative penile erection may be managed by injecting small boluses of an alpha-adrenergic agent (dilute ephedrine or phenylephrine) into the corpora cavernosa.

#### Sepsis

Pre-existing urinary tract infection should always be rectified and managed before undertaking TURP. Patients with longstanding indwelling catheters are at greater risk. Once infection is recognized, broad-spectrum empirical antibiotic therapy is started. Perioperative antibiotic prophylaxis has been shown to reduce the risk of events related to postoperative infection.

### Late complications

#### Bladder neck contracture

This complication occurs 4–6 weeks after surgery and should be suspected in a patient complaining of poor stream who initially had a good flow postoperatively. Zwergel et al. reported bladder neck contracture in up to 2.7% patients following TURP [36]. It can be treated by bladder neck incision with a Collings knife.

#### Urethral stricture

Urethral strictures following TURP have been reported in 1.7% patients and can occur at the fossa navicularis (most commonly), bulbar urethra or prostato-membranous junction [36]. Strictures can be treated with sequential urethral dilatation and optical internal urethrotomy. The incidence of post-TURP stricture has declined significantly with the availability of better electrosurgical equipment and smaller sized resectoscopes, limiting the resection time, and use of lubricant jelly.

#### Incontinence

Thermal injury to the sphincter is the underlying mechanism in most patients who develop this complication of TURP. Detrusor instability and residual adenoma blocking the external sphincter mechanism may also contribute to this complaint. Transient incontinence is relatively common following the procedure, and most patients show spontaneous improvement in a few weeks or months. Kegel exercises and anticholinergics are useful in these patients. For refractory cases, collagen injections and artificial sphincters are needed.

### Impotence

A small number of patients report impotence following the procedure, which may be psychogenic or due to age and prolonged abstinence following the operation. This complication needs to be studied well to eliminate the discrepancy in the reported literature (incidence 4–40%). In fully potent men, the risk of impotence after transurethral prostatectomy is fairly low, but it is higher in men who already have a degree of erectile failure. This risk has also been reported to be related to the incidence of capsular perforation at the time of surgery [37].

Tscholl et al. used the Snap Gauge tests to assess the incidence of erectile impotence in patients with intact potency preoperatively. Of the 98 patients studied, they observed that erectile dysfunction persisted in eight (8.3%) patients three months after the procedure [38]. Importantly, in their study 26 patients who had potency-related problems postoperatively improved in the subsequent three months.

## Comparison with bipolar transurethral resection of the prostate

Monopolar TURP does suffer from a few inherent limitations. First, the patient is a part of the electrosurgical circuit, which can cause deep heating and the possibility of nerve damage. Second, the use of a hypo-osmolar irrigant implies that electrolyte imbalance and TUR syndrome will always remain bothersome concerns.

In recent years, bipolar TURP has emerged as an alternative to the standard monopolar TURP. Advocates of bipolar TURP cite comparable clinical efficacy with a better safety profile, especially in terms of lower instances of TUR syndrome and better hemostatic capability, as the primary reason for its superiority. A systematic review by Tang et al. indicates that bipolar TURP was significantly better for decreasing the incidence of TUR syndrome and clot retention. However no significant differences were observed in the nature of adverse events such as transfusions, retention after catheter removal, and urethral complications between the groups [39].

Another study by Mamoulakis et al. indicated that no clinically relevant differences in short-term efficacy exist between the two techniques, but that bipolar TURP is preferable due to a more favorable safety profile (lower TUR syndrome and clot retention rates) and shorter irrigation and catheterization duration [40].

These studies are promising, but large randomized _ trials with long-term follow-up are needed to further clarify issues related to long-term complications and cost. Bipolar TURP has the potential to become the next generation "gold standard" for benign prostatic obstruction but only time will tell if it can replace monopolar TURP.

# Ablation of Prostate: Bipolar Resection

*Jaspreet S. Sandhu*

## Introduction

Bipolar transurethral resection of the prostate (BiTURP) is an endoscopic technique used in the surgical management of lower urinary tract symptoms (LUTS) secondary to benign prostatic hyperplasia (BPH).

Monopolar TURP, as described in Chapter 150, is a transurethral endoscopic procedure that relies on electrosurgical resection of prostate adenoma, followed by removal of "prostate chips" from the bladder with an aqueous evacuator. It has been performed since early in the last century, has evolved to be the procedure of choice for surgical treatment of LUTS secondary to BPH, and is often called the "gold standard" surgical treatment for BPH/LUTS. Although monopolar TURP is known to be efficacious in this context, it is associated with reasonably high rates of complications, including hematuria, reoperation, dilutional hyponatremia, and the need for blood transfusion [1]. Advances in optics and energy generation/delivery systems have decreased complications significantly in modern times [2]. However, the number of TURPs performed in the United States continues to decrease yearly, perhaps because of the perception of increased morbidity [3].

The rationale for BiTURP, therefore, is straightforward – to limit the risk of dilutional hyponatremia while leveraging transurethral resection skills that most urologist acquire during training and practice. Most authorities suggest limiting monopolar TURP operating times to 60 minutes because absorption of fluid is proportional to the operative time. Longer operative times lead to increasing risk of dilutional hyponatremia, also known as "TUR syndrome" due to absorption of glycine irrigation [4]. The fact that BiTURP uses normal saline as an irrigant effectively eliminates the risk of dilutional hyponatremia and allows operators to use this technique for as long as needed. This is particularly advantageous in patients with large-volume prostates or for use in medical education.

It should be noted that BiTURP is actually an evolution of transurethral vaporization of the prostate [5], which is a monopolar technique that uses higher current and electrodes with broader contact with tissue to "vaporize" tissue at the cut edge of the resection. BiTURP has been referred to as bipolar vaporesection of the prostate, plasmakinetic vaporization of the prostate, or bipolar resection of the prostate. This nomenclature adds to confusion, particularly with strictly ablative techniques such as photoselective laser vaporization of the prostate or bipolar button vaporization electrode. The "vaporization" referred to in BiTURP is actually the vaporization that occurs of tissue in contact with the cutting loop (active electrode). This is similar to what happens to tissue in contact with the cutting electrode during monopolar TURP. BiTURP relies on the creation of a "plasma corona" at the electrode and this results in roughly 20% of the tissue being vaporized, with the rest resected as prostate chips [6].

BiTURP was first introduced in humans in the early part of this century [7]. The initial reports touted this technique's ability to use bipolar current through an isotonic irrigant media with results similar to TURP. Most subsequent reports have focused on technologies from different manufacturers and primarily compared results to TURP via either randomized control trials or comparative trials.

## Patient selection

Surgical therapy is the mainstay for treatment of LUTS secondary to BPH, refractory to medical therapy. Current practice is to offer minimally invasive surgery to patients

*Smith's Textbook of Endourology*, Fourth Edition. Edited by Arthur D. Smith, Glenn M. Preminger, Louis R. Kavoussi, and Gopal H. Badlani.

who do not want or are unfit for a more involved operation. Endoscopic surgery is the gold standard for treatment of LUTS secondary to BPH, with open surgery reserved for those patients with large glands or those who need concomitant procedures [8].

The most recent American Urological Association (AUA) guidelines [8] on the management of BPH/LUTS recommend TURP as the surgical treatment of choice for men with moderate to severe LUTS who are bothered by their symptoms. These guidelines state that the "choice of a monopolar or bipolar approach should be based on the patient's presentation, anatomy, the surgeon's experience and discussion of the potential risks and likely benefits" [8]. The European Association of Urology has similar recommendations in its recently release guideline on the management of non-neurogenic male LUTS, but goes a little further by stating that "B-TURP offers an attractive alternative to M-TURP in patients with moderate to severe LUTS secondary to BPO [benign prostatic obstruction], with similar efficacy but lower peri-operative morbidity" [9]. An updated set of AUA guidelines is currently being formulated and should be available shortly.

## Surgical equipment

BiTURP is an endoscopic resection technique that uses a continuous flow resectoscope and a specially designed loop and inner sheath that varies by manufacturer and use. It is a design modification of the monopolar TURP, utilizing a specialized resectoscope and loop that incorporates the active electrode on the loop and return electrode on a separate insulated part of the loop or on the inner sheath of the resectoscope. This allows the procedure to be performed using normal saline as an irrigant, thereby limiting the risk of dilutional hyponatremia (or TUR syndrome), and with potentially less stray current because of the very short distance between the active and return electrodes. The electrode can be used to resect as well as coagulate. Modifications of the electrode also allow vaporization, which will be discussed in a subsequent section. In contrast to monopolar TURP, the irrigant media is usually 0.9% normal saline. Generators are also matched to the loop used and voltage is varied based on impedance to keep the current constant.

## Technology

Bipolar technology platforms currently available are the PK system by Gyrus/ACMI, an Olympus Corporation (Tokyo, Japan) company, the TURis system by Olympus Corporation (Tokyo, Japan), and a bipolar resection system by Karl Storz (Tuttlingen, Germany). Each of these systems uses a continuous flow resectoscope and relies on an active electrode on the cutting element of the loop, with the ability to generate a plasma corona vaporization field in normal saline media. The difference between these platforms is the location of the return electrode. Because BiTURP relies on the ability to generate a current between two poles and the closer the two poles, the lower the voltage needed to generate a current, the return pole (electrode) has to be in close proximity to the active electrode. As such, the return electrode of the PK system is on the loop itself, separated from the cutting element by a few millimeters of insulation. The return electrode for the TURis system is on the inner sheath of the resectosope, and the return electrode for the Storz system is on the loop opposite the cutting element. See Figures 151.1–151.3 for illustrations of the different available loops.

The BiTURP, which typically needs a lower voltage differential to generate a high current because of the short distance needed to close the circuit, relies on generators that can change voltage based on tissue impedence and therefore keep current constant. Specially designed generators are matched to each platform. All generators have preset default settings; typical settings for "cutting" are high power (200–280 W for TURis, 160–200 W for PK) and settings for "coagulation" are lower power (120 W for TURis and 80 W for PK). Different loops are also available for the PK system and the TURis system to allow resection of bladder tumors or to perform vaporization without resection. All currently available loop electrodes are single use. Figure 151.4 is an illustration of the Gyrus PK® generator.

## Surgical technique

The surgical technique for BiTURP is similar to that for monopolar TURP, with a few unique aspects. As in other transurethral procedures, preoperative antibiotics should be given. Regional anesthesia (e.g. spinal) or general anesthesia may be used. It is important to note that there should be no dilutional hyponatremia with BiTURP, eliminating the need to monitor mental status and allowing general anesthesia to be used at the anesthesiologist's discretion.

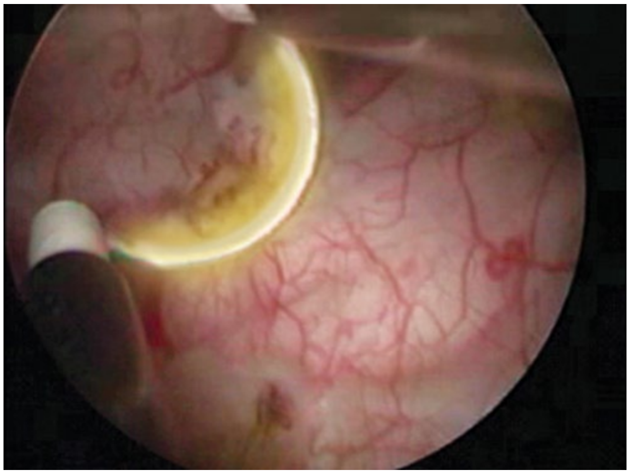

**Figure 151.5** The plasma corona firing in the bladder.

Initial intubation of the urethra should be performed with the help of a visual obturator. If needed, a urethrotomy may be performed to allow entry of larger resectoscopes. Once the bladder is reasonably filled, continuous irrigation should be started, typically with the outflow port open to gravity drainage. Resection is started by first resecting the intravesical component and the median lobe of the prostate. Unlike the monopolar TURP, the cutting electrode loop needs to develop a "plasma corona" prior to the start of resection (see Figure 151.5 for an illustration of a loop with plasma corona active). The loop should be in close proximity to prostate tissue when the operator initiates the cutting current via the foot pedal. At the beginning of the case, this is typically done with the electrode in the bladder and slightly off the prostate surface. Once the corona is formed, resection proceeds in an antegrade fashion for the length of the loop excursion. Prostate chips are formed similar to monopolar TURP and are forced into the bladder by the inflow of normal saline irrigant.

The resection should be performed systematically with prostate landmarks used to limit resection, in particular the verumontanum near the apex. Typically, the intravesical component is first resected, followed by the median lobe from the bladder neck to verumontanum. Care should be taken to avoid injury to the ureteral orifices during this step. Next, one of the two lateral lobes is resected in its entirety prior to proceeding to the other one. Finally, apical tissue and anterior tissue is resected. During resection, the plasma should always be visible. This is especially important as the procedure proceeds, because the cutting loop will add charred tissue to its surface and add impedence to the circuit. As stated above, the corona should be initiated within the bladder or in the lumen of the prostatic urethra without contacting prostate tissue. If the time between stepping on the cutting pedal and the formation of the plasma corona starts to become long, the operator should place the loop in the center of the bladder and allow the plasma to fire for a few seconds. This will clean the loop electrode and allow more efficient vaporization.

Once the surgical endpoint is reached, specifically the entire adenoma has been resected from bladder neck to verumontanum and capsular fibers are visible, hemostatis should be achieved. This is done with the coagulation current. During coagulation, no plasma is formed. Instead of point coagulation, as in monopolar TURP, BiTURP relies on coagulating a surface around the bleeding vessel. This is likely due to the shallow penetration of current during BiTURP. Of note, coagulation should be performed intermittently throughout the procedure if significant bleeding is encountered as this will improve visibility during the case.

Prostate chips deposited in the bladder throughout the resection are removed near the end of the case with help of an aqueous evacuator. Once all chips have been removed and this has been confirmed by a final survey of the base of the bladder and prostate fossa, a three-way urethral catheter is inserted and continuous bladder irrigation is begun. Typically, this irrigation is titrated off by the first postoperative day, and the catheter removed. Patients are discharged with a few days of antibiotics. The prostate chips are evaluated by surgical pathologists in a manner similar to prostate chips removed during a monopolar TURP and the same conventions are used to report findings, including T1a or T1b prostate cancer in cases of previously unsuspected prostate cancer. If T1a or T1b prostate cancer is found and the patient is a candidate for prostate cancer treatment, a prostate biopsy should be performed once the patient has healed from the BiTURP – typically six weeks to three months after the procedure.

Postdischarge management is similar to that with monopolar TURP and is dependent on the surgeon. Typically, patients can expect mild hematuria which resolves within days and can also expect temporary increase in frequence and urgency of urination. There may be a period of recurrent hematuria 2–6 weeks after the procedure, managed by increasing oral hydration. Follow-up visits are usually at 3, 6, and 12 months. At each follow-up visit, the International Prostate Symptom Score (IPSS) is collected along with uroflowmetry data and measurement of postvoid residual urine (PVR). A serum PSA should be obtained at the 12 month visit if indicated. Of note, if patients were candidates for prostate cancer screening at the time of BiTURP, a preoperative serum PSA and digital rectal exam should have been performed and if either one was abnormal, a prostate biopsy should also have been performed.

## Efficacy

The first reports of BiTURP in humans came in the early part of this century. Botto et al. [7] published a pilot study in 2001 of 42 patients who underwent electrovaporization of the prostate using saline bipolar electrocautery using the Gyrus system. These investigators reported three-month results following treatment of men with symptomatic BPH without suspected prostate cancer. They noted that no men had significant postoperative bleeding and the mean catheterization time was 1.4 days. Two out of the 42 patients developed urethral strictures requiring treatment. Mean length of stay was 2.2 days. At three months, IPSS decreased from 16 at baseline to 9 and peak flow rate on uroflowmetry increased from 7.9 ml/s to 19.7 ml/s. Based on these short-term results, the authors concluded that the Gyrus system for electrovaporization of the prostate is useful and safe.

Yang et al. [10] subsequently performed a randomized prospective study comparing the Gyrus BiTURP to conventional monopolar TURP. They enrolled 117 patients, 58 in the BiTURP group and 59 in the monopolar TURP group, and followed these patients for three months. The authors noted that both groups reported significant improvements in IPSS (BiTURP: 20.9 preoperatively to 10.8 at three months; TURP: 21.6 preoperatively to 11.1 at three months) and peak flow rates (BiTURP: 10.4 ml/s to 17.1 ml/s; TURP: 10.9 ml/s to 14.8 ml/s), but noted no statistically significant difference between groups. In their study, complications occurred at the same rate in both groups; notably, only one patient developed TUR syndrome in the monopolar TURP group and none in the BiTURP group. These authors concluded that monopolar TURP and BiTURP yielded similar results but that longer follow-up was necessary to establish long-term efficacy.

Starkman and Santucci [11] retrospectively reviewed their results and compared 18 consecutive patients who underwent monopolar TURP with a subsequent consecutive group of 25 patients who underwent BiTURP. After an observation period of approximately 1.5 years to evaluate long-term complications, weights of resected tissue were similar in both groups; catheterization times were shorter (3.2 days for monopolar TURP vs. 1.8 days for BiTURP) and length of stay shorter with BiTURP (2.1 days for monopolar TURP vs. 1.2 days for BiTURP). Acute complications included 2 out of 18 monopolar TURP patients with dilutional hyponatremia and, interestingly, one out of 25 BiTURP with dilutional hyponatremia. Other acute complications were minor, but higher in the monopolar TURP group compared to in the BiTURP group (33% vs. 16%). Long-term complications consisted of one bulbar urethral stricture in each group and a patient who developed a bladder neck contracture related to radiotherapy for a subsequent prostate cancer diagnosis in the BiTURP group and a patient with persistent stress urinary incontinence in the monopolar TURP group. Long-term complications were not statistically different between groups.

De Sio et al. [12] randomized 70 patients to Gyrus PK BiTURP or monopolar TURP groups. They reported results of their randomized cohorts after 12 months. Like the earlier groups, they found decreased mean catheter time (100 hours for monopolar TURP vs. 72 hours for BiTURP) and mean length of stay (107 hours for monopolar TURP vs. 78 for BiTURP) in the BiTURP group. They also noted no difference between groups in IPSS, peak flow rates, or PVR. IPSS decreased from 20 preoperatively to 4 at 12 months in both groups, peak flow rate improved from roughly 5 ml/s preoperatively to 20 ml/s at 12 months in both groups, and PVR decreased from roughly 80 ml preoperatively to roughly 20 ml at 12 months in both groups. These authors noted no significant difference in adverse events.

Seckiner et al. [13] similarly performed a randomized study comparing the Gyrus PK BiTURP to monopolar TURP. They compared 24 patients in each group and followed them for 12 months. No significant difference in operative and perioperative data were found except for decreased serum sodium in the monopolar TURP group, with two patients in the monopolar TURP group exhibiting mild dilutional hyponatremia. Like previous authors, these authors reported significant improvements in IPSS, peak flow rate, and PVR in both groups compared to baseline values but did not show any difference between groups.

Iori et al. [14] performed a clinical and urodynamic evaluation in a randomized manner to compare Gyrus PK BiTURP to monopolar TURP. These authors operated on 51 patients with urodynamically proven bladder outlet obstruction; 26 of these patients underwent monopolar TURP and 27 underwent BiTURP. Mean follow-up was 12 months. There was no difference in resection time, catheterization time, or length of stay between groups and no difference in change in serum hemoglobin or serum sodium between groups. Of note, all patients underwent urodynamic evaluation prior to procedure and at 12 months postoperatively. The Schaefer obstruction class was significantly improved after both procedures and, as with other parameters, there was no difference between urodynamic effects after monopolar TURP and BiTURP.

Fagerström et al. [15] performed a randomized trial comparing operative performance of the Olympus TURis BiTURP to conventional monopolar TURP. These investigators randomized 202 patients, 185 of whom were evaluable. They noted that both groups had similar tissue resection weight, but that blood loss and hemoglobin decrease were greater in the TURP group than the BiTURP group. These authors concluded that BiTURP causes less bleeding than monopolar TURP technique.

Ho et al. [16] performed a randomized study comparing Olympus TURis BiTURP to standard monopolar TURP and followed these patients for 12 months. They compared 52 patients in the monopolar TURP group to 48 patients in the BiTURP groups and noted no difference in resection time or resection weight. A significant decrease in serum sodium was noted in the monopolar TURP group compared to BiTURP, and two cases of clinically significant dilutional hyponatremia occurred in the monopolar TURP group and no cases in the BiTURP group. Urethral strictures were observed in 3 out of 48 patients in the BiTURP group and 1 out of 52 patients in the TURP group. These authors also showed significant improvements in IPSS and peak flow rate at 12 months from baseline in both groups but no differences between groups. It was concluded that monopolar TURP and BiTURP were equally efficacious with BiTURP having a better safety profile.

Michielsen et al. [17] performed a large randomized trial comparing conventional monopolar TURP to Olympus TURis BiTURP. One hundred and twenty patients underwent monopolar TURP and 118 underwent a BiTURP. These authors focus on intraoperative parameters and immediate perioperative morbidity. They noted no difference is resected prostate tissue weight and duration of hospitalization between groups. They did note that BiTURP took longer to perform, but that decrease in serum sodium was significantly greater for the monopolar TURP group. They also noted one case of TUR syndrome in the monopolar TURP group and none in the BiTURP cohort.

BiTURP has been reported to be a safe alternative to monopolar TURP for use in resident teaching and for the management of large-volume prostates. Bhansali et al. [18] performed a randomized trial of 70 patients with prostate sizes greater than 60 g comparing Gyrus PK BiTURP to monopolar TURP. They noted no length of stay or function outcomes at 9 and 12 months postoperatively between the two cohorts. They did notice significantly more blood loss, significantly longer catheterization time, and significantly large changes in serum sodium in the monopolar TURP group compared to the BiTURP group. The authors concluded that it is safe to perform BiTURP in large-volume prostates.

More recently, Demirdag et al. [19] reported on 81 patients with prostates greater than 60 ml, 45 of whom underwent monopolar and 36 underwent BiTURP, and noted that the only difference between the two groups was a decrease in serum sodium in the monopolar group. Further, the authors noted that two of the monopolar patients had TUR syndrome whereas none of the BiTURP patients did.

Gilleran et al. [20] commented on using BiTURP in an academic setting to help teach residents how to perform an adequate TURP. These authors reported results of a series of 21 men who underwent Gyrus PK TURP in an academic setting. They noted that despite small-size prostates (median resected tissue weight was 20 g), they had a median resection time of 65 minutes, which is much more than would be expected for the amount of tissue resected. Although they did note a significant decrease in serum hemoglobin between preoperative and postoperative values, they did not report a significant difference in serum sodium and no patients needed blood transfusions. The authors concluded that BiTURP is a safe modality for resident medical education.

Large series of BiTURP have been reported recently. Martis et al. [21] reported their series of 401 patient who underwent Gyrus PK BiTURP and noted no intraoperative complications. They reported excellent and durable functional results measured by IPSS and peak flow rates though 36 months of follow-up. The authors did note three patients developed urethral strictures that were effectively managed with internal urethrotomy. Puppo et al. [22] reported outcomes and complications after the first 1000 cases of Olympus TURis system resections, including 376 BiTURPs. Other procedures using the saline bipolar technology in this report were 480 bladder tumor resections and 144 transurethral incisions of the prostate. The authors noted no cases of TUR syndrome and operative and function results better than comparable series of monopolar TURP.

Mamoulokis et al. [23] reported a systematic review and meta-analysis of all randomized control trials of BiTURP. They found a total of 16 randomized controlled trials with 1406 patients which were included in the meta-analysis. The authors noted that efficacy of BiTURP was comparable to monopolar TURP, with respect to IPSS and quality-of-life metrics. They did note, however, that peak flow rate was significantly improved with BiTURP over monopolar TURP at 12 months. This was weighted by one trial which showed marked improvements for BiTURP over monopolar TURP. The meta-analysis also evaluated decreases in serum sodium and incidences of TUR syndrome. They noted a significant larger difference in serum sodium decrease in patients undergoing monopolar TURP compared to BiTURP. Of note, while none of the individual studies showed a difference in the incidence of TUR syndrome, the pooled analysis did detect a significantly higher rate of TUR syndrome in patients who underwent a monopolar TURP compared to a BiTURP. The number needed to treat to prevent one case of TUR syndrome was 50.

Lee et al. [24] and Omar et al. [25] subsequently performed systemic reviews and noted somewhat differing results. Lee et al. found improvements in IPSS, maximum flow rates, residual volume, better satisfaction, and decreased complications in the BiTURP patients, whereas Omar et al. noted decreased complications but no significant improvement in efficacy in the BiTURP. They also noted no significant difference in IPSS and while there was a significant difference in maximum urinary flow there was evidence of heterogeneity between groups.

Cornu et al. [26] recently published a comprehensive systemic review that evaluated functional outcomes and complications following multiple transurethral procedures for LUTS. When comparing BiTURP to monopolar TURP, the authors noted complication rates were lower in the BiTURP patients but that efficacy was similar between groups.

## Morbidity/complications

BiTURP appears to be safer than monopolar TURP, especially with regard to decreases in serum sodium and incidence of dilutional hyponatremia. All studies that report on serum sodium show decrease and the meta-analysis performed by Mamoulokis et al. [23] confirmed that serum sodium decreases and incidences of TUR syndrome are both significantly higher in monopolar TURP arms as compared to BiTURP. BiTURP has not been compared to other prostate ablation modalities such as laser prostatectomy that also use normal saline as an irrigant.

Urethral strictures were noted to be higher in the early BiTURP studies, particularly in a study by Tefekli et al. [27] that evaluated a hybrid vaporization/resection technique using Gyrus equipment. These authors compare their saline bipolar technique to monopolar TURP and noted similar efficacy but a significantly higher rate of urethral strictures in the bipolar cohort. Other authors have suggested that the large cystoscope needed to perform continuous flow BiTURP and possibly longer operating times may be associated with increased incidence of urethral strictures [17]. A unique aspect of Olympus TURis BiTURP has also been implicated – the fact that current returns through the inner sheath [16]. An equipment malfunction could potentially expose the urethra to active current, potentially leading to urethral strictures. Despite the fact that the cutting loops for TURis are single use, some authors have speculated that reusing the loops leads to higher stricture rate. The pooled analysis of all BiTURP randomized control trials [23] has not shown a higher rate of urethral stricture, and in fact shows stricture and bladder neck contracture rates comparable to those of BiTURP and monopolar TURP. Mamoulakis et al. [28] performed a multicenter RCT of 295 patients comparing BiTURP to monopolar TURP and found 10 urethral strictures in each arm, but noted two bladder neck contractures in the monopolar arm compared to eight in the BiTURP arm. The differences in bladder neck contractures, however, was not significant.

The perception of increased intra- and postoperative blood loss with BiTURP remains controversial. Although early reports after saline bipolar resection showed a smaller zone of coagulation than monopolar TURP [29], more recent report have shown a larger zone [30] and others have shown differences in size of zone between that measured immediately postoperatively and that measured after a few days [31]. It remains unclear which is beneficial as far as hematuria is concerned – decreased or increased zone of coagulation. Regardless, the pooled meta-analysis [23] showed no difference in intraoperative or postoperative blood loss following BiTURP compared to monopolar TURP. Stucki et al. [32] performed an RCT comparing bipolar to monopolar focusing on bleeding complications and noted no significant difference in blood loss, rates of blood transfusion, or TUR syndrome, but did note a significantly higher rate of bladder neck contracture in the biTURP arm (8.5% vs. 0%).

Rates of TUR syndrome are certainly lower for BiTURP than monopolar TURP due to absorption of isotonic instead of hypotonic irrigant media. However, fluid absorption does occur with BiTURP and Porsch et al. [33] showed that this absorption is higher in patients who undergo BiTURP than in those who undergo photoselective laser vaporization of the prostate, even though both procedures use normal saline as irrigant. This means that care should be taken when performing BiTURP in larger glands because of the potential for fluid overload.

## Cost

The cost of BiTURP is an important consideration, especially with pressures on most healthcare systems to control costs. The Urologic Diseases in America project estimated that over US$1 billion was spent in the United States for the management of BPH, not including costs of medicines [3]. It appears that BiTURP may be less expensive than monopolar TURP despite increased capital costs and increased disposable costs. This has been postulated to be because of potential decreased length of stay and possibly decreased postoperative complications due to BiTURP.

BiTURP has not been compared to other modalities for prostate debulking, but is likely to be at least competitive when it comes to other methods of prostate ablation. The fact that BiTURP is a technique that most urologists have learned in graduate medical education may decrease the training costs associated with learning newer techniques such as laser prostatectomy. However, these new modalities may offer similar improvements in length of stay and morbidity as compared to BiTURP, as BiTURP did compared to monopolar TURP. Whether the differential in these recurring costs is greater than initial capital outlay remains to be seen.

## Education issues

The BiTURP has been touted as a useful adjunct for urology graduate medical education [6, 20] because the decreased risk of dilutional hyponatremia leaves more time available for resident operative teaching. Although this is a valid observation, it should be noted that the number of transurethral resections of the prostate, monopolar or bipolar, have been declining for decades [3]. In fact, over a 7-year period during which BiTURP was available, graduating chief residents performed approximately 25% fewer cases [34]. This might be due to increase in other ablative treatments such as laser prostatectomy and may be a reversible trend if BiTURP is adopted by the urologic community.

A more fundamental question is the role of TURP in management of BPH/LUTS. With the advent of effective medical therapy and a host of other ablative and minimally invasive techniques available for the surgical management of BPH/LUTS, the TURP procedure may be performed less and less often and therefore may not remain the "gold standard." If this were to happen, some of the advantages of the BiTURP may become less obvious.

## Conclusions

BiTURP is an effective modality for the surgical management of BPH/LUTS. It has been in use for only about a decade and during that time it has demonstrated efficacy similar to that of monopolar TURP, with potentially improved safety profile. It has not been compared to other transurethral ablative therapies for the prostate that use saline as an irrigant. If TURP remains the "gold standard" for surgical management of BPH/LUTS in the future, then BiTURP will continue to have an increasing role.

## Introduction

Transurethral resection of the prostate (TURP) has long been accepted as the "gold standard" surgical treatment for benign prostatic hyperplasia (BPH). It is the measuring stick against which all other minimally invasive treatments for BPH are compared, being highly effective in improving urinary flow rates and decreasing symptom scores. The Agency for Health Care Policy and Research (AHCPR) panel guideline meta-analysis showed that patients had an 88% chance of symptomatic improvement after TURP [1]. However, due to the morbidity associated with monopolar TURP, including the risk of bleeding, clot retention, impotence, urethral stricture, and transurethral resection (TUR) syndrome, as well as the length of hospitalization and catheterization, urologists have been tinkering with other minimally invasive treatments for BPH for decades.

Vaporization of the prostate was first described in the early 1990s using either conventional electrical surgery, termed electrovaporization, or laser techniques [2]. Transurethral vaporization of the prostate (TUVP) was first described by Kaplan and Te in 1995 [3]. The proposed advantages of TUVP included less blood loss, shorter catheterization time, and shorter hospitalization, all the while maintaining efficacy. Initially, electrovaporization techniques were performed using monopolar currents, but a monopolar current has its own associated problems. First, the use of a conductive irrigant, such as glycine or mannitol, is required, which may result in systemic absorption of hypotonic fluids, thus risking hyponatremia and TUR syndrome. Second, the patient is part of an electrical circuit that can pose a risk for patients with pacemakers and cause diathermy burns at the site of the return plate. Third, monopolar current does not allow simultaneous cutting and coagulation. To address these issues, bipolar electrocircuitry was developed for minimally invasive prostate surgery. Bipolar vaporization or resection allows normal saline to be used, which is isotonic, avoids the need for a return plate as the patient is not part of the electrical circuit, and allows simultaneous cutting and coagulation.

Bipolar electrovaporization of the prostate was first described in 2001 using a Gyrus device [4]. Since then, numerous centers have reported level 1 evidence for favorable short-term outcomes using bipolar vaporization of the prostate. Herein we present a review of the mechanism of action of bipolar vaporization, various electrode and generator designs, clinical experience, and relevant comparative studies.

## Mechanism of action

Vaporization is produced via the application of energy to the prostate, which results in heating of the tissues. The tissues are primarily composed of intracellular water, which subsequently boils at a rapid rate, thus producing steam. This results in cellular disruption and tissue destruction, leaving a void where the cells were previously present. In electrosurgery, the rate of electrical energy delivered ($W$) is measured in watts, the current ($I$) flows through the tissue, and the tissue creates electrical impedance ($R$). Heat is created due to the electrical impedance of the prostate to current flow, therefore:

$$W = I^2/R$$

Most of the energy delivered to the prostate results in vaporization of the surface layer of cells; however, some of the energy has been shown to disperse below the vaporization layer to create a zone of coagulation, resulting in improved hemostasis. This phenomenon of simultaneous

Companion website: www.wiley.com/go/smith/textbookofendourology

vaporization/ablation and coagulation is the principal benefit of TUVP techniques. The actual depth of coagulation depends on system and electrode design. The technique employed by the surgeon will also impact the depth of coagulation as this is increased by increased pressure on and time in contact with the tissue. Importantly, coagulation has to take place with bipolar technology at lower peak voltages compared to those used for monopolar surgery (80–100 V for the PlasmaKinetic™ (PK) system) as higher voltages will convert the liquid into a gaseous phase, resulting in higher impedance. The impedance therefore is changed from a resistive to a capacitive mode, reducing energy flow, dissipating heat, and decreasing the final coagulation effect.

In bipolar and monopolar cutting, the generator must initiate a momentary high-energy spike to initiate a plasma vapor layer. This layer is ionized in the form of a nonequilibrium plasma, where plasma ions and electrons are responsible for current flow. In monopolar circuitry, the current arcs to the tissue and passes through the patient to a large-surface return electrode on the skin, heating the intervening tissue by ohmic resistance. However, in bipolar surgery, the active and return electrodes are in close proximity to each other, separated by an insulator. The electron emission from the smaller active electrode heats and vaporizes the adjacent intracellular water to form a thin gas layer (plasma pocket) that grows and forms a larger bubble containing energetic species that can dissociate both water and organic molecules, resulting in the net tissue effect [5]. It is likely that the thermal effect noted with bipolar surgery takes place at much lower temperatures (<70 °C) than those in monopolar surgery (300–400 °C). Once the plasma vapor pocket is formed, it can be maintained at low voltages (100–350 $V_{rms}$) as the electrode is close to making contact with the tissue. Tissue destruction ensues due to the breakdown of carbon–carbon and carbon–nitrogen bonds. This results in the production of elementary molecules and low molecular weight gases, including carbon dioxide, oxygen, nitrogen, and hydrogen. Intraoperatively, the effect is precise cutting and vaporization with minimal collateral damage as the charged sodium ions contained within the plasma vapor pocket have only a short estimated range of penetration (50–100 μm). This is largely due to electrosurgical principles as minimization of collateral tissue damage is dependent upon resistive heating caused by any current flowing through tissue and by limiting thermal transfer from the electrode sources. The final result in the human prostate is precision tissue cutting/vaporization with minimal charring and burnt prostate odor traditionally equated with monopolar TURP.

Specialized generators were developed along with the bipolar technology using radiofrequency (RF) energy output. The initial bipolar vaporization of the prostate used a Gyrus device and generator designed with a 200 W capability with an RF range of 320–450 kHz and a voltage range of 254–350 V [4]. However, the Vista Coblation system (ACMI Corporation, Southborough, MA, USA) used RF energy output from a specialized electrosurgical generator that is one-fifth that of monopolar generators (100 kHz square wave) [6]. The initial Olympus SurgMaster generated an RF output of 350 kHz and a recent report used the UES-40 SurgMaster (Olympus Medical/Winter & Ibe GmbH, Hamburg, Germany) with a power output of 290 W and 120 W for vaporization and coagulation, respectively (Figure 152.1) [7]. The frequency of the newest system from Karl Storz (Autocon® II 400 Electrosurgical System, Karl Storz, Tuttlingen, Germany) (Figure 152.2) generates an RF output of 350 kHz with a power output of 120 W for coagulation.

## Electrode and generator design

The bipolar technology was developed with the active and return electrodes in close proximity to one another, separated by an insulator. Energy from the generator travels through the active electrode, through the plasma pocket, through the conductive solution to the tissue bed, and returns via a thicker electrode to the active cord to the ground. Hence, there is no need for any energy to travel through the patient to a return electrode on the skin, eliminating the risk for inadvertent burns from inadequate contact. Also, the low operating frequency and voltage of bipolar surgery should eliminate any potential for interference with cardiac pacemakers.

There are several challenges to electrode design, including establishment of a reliable plasma corona preferentially at the distal active electrode, how to achieve a plasma condition with short delays from the time of foot-switch activation by the surgeon, how to provide adequate hemostasis from both cut and coagulation sources of foot-switch operation, and how to maintain this under all surgical conditions. With these challenges in mind, manufacturers and urologists are still in search of the “ideal” electrode for bipolar TUVP. The commercially available electrodes vary in size and configuration; however, in general, the active component is slightly thinner and separated from the thicker return electrode component by an insulator. The commercially available systems also vary in terms of resectoscope sizes, design of electrode housings, and coupling mechanism between active and return cords.

The Gyrus PK system was the first bipolar vaporization technology reported in the literature and therefore had to address several of these early technical issues. For bipolar vaporization to occur at the time of foot-pedal activation,

the active electrode must be in close proximity to the tissue because if the gap is too wide or if there is insufficient power, current flow is dissipated by the large volume of electrolyte solution in a full bladder and there is no effect on the tissue. Furthermore, if the power/voltage spike is not great enough to maintain the plasma pocket, cutting and vaporization of the tissue will occur in a stuttering fashion, depending on the quality of tissue contact.

With these limitations and challenges in mind, the initial Gyrus PK system was modified, resulting in a second-generation model called the PK SuperPulse® Generator. There are several advantages of this system. First, this device is preconfigured for maximal allowable current under low impedance conditions. Second, the surgeon can choose between two sets of preset cutting voltages. Third, the generator is designed to recognize the active electrode offering default settings that are optimal for a wide range of conditions at the tip. Lastly, the PK SuperPulse generator is equipped with a row of internal capacitors acting as an energy reservoir to ensure sufficient voltage for instantaneous fire-up and for power ride-through under challenging conditions of impedance. These modifications have resolved the issue of stuttering cutting/vaporization that occurred previously. The capacitor reservoir can provide up to 4000 W of power for short periods of time (10 ms) if the tip impedance is low enough. This may be important because under conditions of high flow with cold saline, more power than normal is required to create and maintain the initial plasma pocket at the active electrode tip.

At baseline, prior to RF voltage application, the impedance differential between bipolar active and return electrodes is between 23 and 60 ohm with variability due to the irrigation temperature and the proximity of the active electrode to the tissue bed. The PK SuperPulse generator can generate a high enough power (4000 W) at low impedance (23 ohm) to sustain a voltage of close to 300 $V_{rms}$ that boils the saline immediately surrounding the active loop in a matter of milliseconds. This phenomenon is largely due to the electrode design. The electrical current crowds the reduced surface area of the active electrode, which results in a nonequilibrium vapor pocket containing charged sodium ions. The activated sodium ions form the plasma inside the vapor pocket and produce the orange glow that is visible to the naked eye. There is a time delay of 1–2 μs from the initial negative current spike until light is emitted. Once the plasma is formed, the impedance increases greatly from 500 to 3000 ohm, depending on whether the electrode is in contact with the vapor pocket or the irrigant, and/or the length of the vapor pocket (as there is higher impedance with longer plasma vapor pocket lengths). The power delivery now becomes focused around the active electrode and is not dissipated in the surrounding saline solution and prostate tissue, and therefore much less power is required to sustain the plasma vapor pocket. The energy reservoir can then be replenished as the output voltage falls by being repeatedly formed during each half cycle of the high-frequency exciting voltage waveform.

The PK SuperPulse generator has two sets of preset cutting voltages (termed SP1 and SP2). At the lower preset voltage of SP1, plasma volume is smaller and impedance is lower, and detected intraoperatively as a less intense orange glow around the active electrode. The SP2 setting can be used during suboptimal operative conditions when cutting/vaporization becomes difficult, to allow for an increased plasma volume and slightly higher preset voltage. Foot-pedal activation and fire-up should take no longer than 20 ms as a result of the energy reservoir of the internal capacitors. Once an activated electrode is in contact with tissue, *in vivo* studies have demonstrated that no more than 100 W are usually required to sustain the user-defined maximum voltages.

## Clinical experience

Bipolar TUVP has been in clinical use for a decade. The initial experience was reported in 2001 by Botto et al. using the Gyrus device and a rolling-type electrode (Axipolair®) [4]. This pilot study utilized the first-generation Gyrus PK generator and the electrode consisted of an active component (manufactured from 80/20 platinum/iridium alloy) and a return electrode (manufactured from stainless steel) placed on the same axis. A ceramic insulator separated the active and return electrodes. The initial technique describes vaporizing the obstructing tissue by placing the electrode in direct contact with the prostate in a systematic fashion similar to the technique for traditional TURP. The two major differences in performing bipolar TUVP are the modeling of the prostatic cavity in a circumferential action and the need to activate the current prior to bringing the electrode into direct contact with the tissue to allow the vapor pocket to build up. Therefore, for experienced endoscopists, the learning curve for bipolar TUVP is quite minimal. Forty-two patients with symptomatic BPH were included in this study and underwent bipolar TUVP using a standard 27 Fr resectoscope sheath and normal saline as irrigant. A majority of the patients (19) had a prostate volume between 30 and 60 ml and 93% of the operations took less than 60 minutes to complete. The mean postoperative hospitalization (including the day of surgery) was 2.2 days and all patients passed a voiding trial prior to discharge home. Early complications included bulbar urethral stricture in two patients requiring endoscopic urethrotomy, and dysuria in four patients, two of whom complained of dysuria for three months. Functional outcomes were assessed with International Prostate Symptom Score (IPSS) and maximum flow rate ($Q_{max}$) at baseline and at three months. Mean IPSS decreased from 19 to 9 and mean $Q_{max}$ increased from 7.9 ml/s at baseline to 19.7 ml/s at three months. These early clinical results showed feasibility, safety, and acceptable short-term outcomes that warranted further study.

Eaton and Francis performed bipolar TUVP in 40 patients with BPH symptomatology in a day surgical unit setting in the United Kingdom [8]. Similarly, bipolar TUVP was carried out using the Gyrus PK tissue management system (Gyrus Medical Ltd, Buckinghamshire, UK), which involved a 27 Fr continuous flow resectoscope sheath and normal saline irrigation. The mean operative time was 33 minutes (range 12–52 minutes) and mean prostate volume was 34.9 ml (range 15–76 ml). No patients had any electrolyte abnormalities or significant drop in hemoglobin level postoperatively. All but six patients were discharged home on the day of surgery, with an average hospital stay of 5.9 hours. All patients voided successfully at 48 hours, but two returned with obstructed catheters, thought to be due to coagulum and not blood clot or tissue fragments. At four months there was an improvement in IPSS and quality of life (QOL) by 64% and 83%, respectively, and an improvement in mean flow rate of 200%, but no baseline data were reported in any of these categories.

Dincel et al. reported on their initial experience with bipolar TUVP using the Gyrus PK tissue management system and a Plasma-V™ electrode (Figure 152.3) [9]. Twenty-one men with moderate to severe lower urinary tract symptoms (LUTS) attributable to BPH underwent bipolar TUVP, of whom 20 returned for follow-up and were available for final analysis. The median prostate volume was 42 ml and the operative time increased as the size of the prostate increased (median 55 minutes). The median duration of catheterization and time to discharge was three days. The only perioperative complication reported was constipation in one patient who required readmission due to clot retention and was transfused two units of blood. Median IPSS and urine flow rates were significantly better at 90 days postoperatively, and postvoid residual urine volume (PVR) had significantly decreased from a median of 54 ml to 19.5 ml. Serum prostate-specific antigen (PSA) values were measured preoperatively, on postoperative day 1, 30 days postoperatively, and 90 days postoperatively. Serum PSA values were significantly increased on postoperative day 1, and then trended back towards preoperative levels by 90 days postoperatively, prompting the authors to suggest that serum PSA levels should not be obtained in patients who have undergone bipolar TUVP until at least 30 days postoperatively. Furthermore, in these early studies, patients were heavily screened preoperatively for prostate cancer with serum PSA measurements and digital rectal examination (DRE), as it is important to note that no tissue is retrieved from TUVP for pathologic analysis. Therefore, patients with abnormal PSA/DRE were excluded from participation in these studies. Although the results of these nonrandomized clinical trials were promising and sparked the interest of the urologic community, large randomized prospective trials with long-term follow-up were needed to provide better evidence-based medicine rationale for the use of this new technology.

## Comparative studies

In 2003, Dunsmuir et al. reported the first randomized prospective clinical trial comparing bipolar TUVP to traditional monopolar TURP [10]. This study randomized 51 men with LUTS secondary to BPH to bipolar TUVP ($n = 30$) versus monopolar TURP ($n = 21$), of whom 40 (20 in each group) completed follow-up at 1 year. The bipolar TUVP arm underwent vaporization using a similar technique to that previously described using the Gyrus PK device with the Axipolaire electrode, and monopolar TURP was performed using standard techniques. In terms of perioperative outcomes, there was no difference in operative time, irrigation time, and time to catheter removal, or length of hospital stay between the two groups. These patients were followed up 1 year later and improvements in IPSS, flow rates, PVR, and QOL were similar between the two groups. Interestingly, four patients in the TURP group compared to zero patients undergoing TUVP required manual clot evacuation in the postoperative period, but the recatheterization rate for the TUVP procedure was 30% (compared to 5% for traditional TURP). All patients voided successfully 2–3 weeks later (range 14–19 days).

Hon et al. performed a randomized prospective clinical trial on 160 consecutive patients in their practice undergoing transurethral prostatectomy for bladder outlet obstruction [11]. They randomized the men to traditional TURP ($n = 81$) versus bipolar TUVP ($n = 79$) using the Gyrus PK system and the Plasma-V bar electrode. The two groups were similar preoperatively with regard to baseline characteristics. Mean operative time was 4 minutes shorter in the TURP arm, but this was not statistically significant (28.5 vs. 32.6 minutes, $P = 0.08$). There was no significant difference between the two groups with respect to intraoperative blood loss; however, the TURP group had a greater hemoglobin decrease postoperatively (1.4 vs. 0.8 g/dl, $P = 0.002$). Likewise, the TURP patients required more irrigant (28.3 vs. 20.1 liters, $P = 0.001$) and more manual bladder irrigations postoperatively (31 in 11 patients compared to 11 in seven patients who underwent TUVP, $P = 0.27$). The only difference in short-term adverse events included a total of 14 units of blood transfusion in the TURP arm compared to zero units of blood transfusion in the TUVP arm. The hospital stay was significantly longer for patients who underwent TURP compared to TUVP (3.4 vs. 3.0 days, $P = 0.04$). Interestingly, despite rigorous preoperative screening, eight patients in the TURP arm were found to have prostate carcinoma detected on prostate chip histology. Long-term outcomes were available in 93% of the patients at a mean follow-up of 258 days. IPSS, QOL, PVR, and $Q_{\max}$ improved significantly regardless of technique; however, there was no statistically significant difference detected in any of these categories other than for average urine flow when comparing TURP to bipolar TUVP. This fairly large trial with a decent length of follow-up concluded that bipolar TUVP has equivalent outcomes to monopolar TURP but with fewer earlier complications.

The disadvantage of bipolar TUVP is the lack of tissue for histologic processing. It is important to note that some clinically significant cancers may be missed, therefore highlighting the importance of screening these patients preoperatively and following them postoperatively with serial serum PSA and DRE.

Due to the potential for missing cancer and lack of tissue obtained from pure vaporization techniques, researchers began exploring a possible hybrid technique. This technique combined bipolar vaporization of the prostate with bipolar resection (TUVRP) and was described by Tefekli et al. in 2005 [12]. It should be pointed out that other researchers have shown that tissue sampling with a resection loop after vaporization of the prostate may not increase the likelihood of cancer detection [13]. In this randomized prospective clinical trial, 50 patients undergoing surgery for BPH were randomized to standard monopolar TURP and 51 patients were randomized to the hybrid bipolar TUVRP technique. The bipolar TUVRP procedure was performed with the Gyrus PK system using saline for irrigation. The lateral and median lobes were removed with a vaporization electrode and the final resection of tissue tags and apical tissue around the verumontanum were removed with a resecting loop. This technique was employed to not only remove tissue for pathologic analysis but also to aid delicate tissue resection around the apex and verumontanum. Complete data were available on 96 patients with a mean follow-up of 18.3 months (range 12–23 months). Mean operative time, catheterization time, and hospital stay were significantly lower in the TUVRP group compared to the TURP group. Mean improvement in $Q_{\max}$ was significantly better in the TUVRP group at 12 months, but mean improvement in IPSS from baseline was equivalent between the two groups. However, these authors did note an increase in irritative symptoms and recatheterizations in the TUVRP group, which, they hypothesized, was due to increased tissue edema due to the higher current with lower frequency exerted on the tissue. Of the three patients in the TUVRP group who required recatheterization, all were able to void after seven days. The increased recatheterization rate paralleled the findings of Dunsmuir et al. [10]. Urethral stricture was also a more common complication in the TUVRP group (three TUVRP vs. one TURP, $P = 0.002$) and was successfully managed endoscopically in all patients. The reoperation rate for persistent obstructive symptoms was not statistically significant, likely due to the low number of events in each group, with two patients in the TUVRP arm and only one in the monopolar TURP arm.

With several randomized prospective clinical trials emerging in the literature comparing bipolar TUVP to monopolar TURP, Neill et al. elected to compare holmium laser enucleation of the prostate (HoLEP) to bipolar TUVP in a randomized prospective clinical trial [14]. Forty patients were randomized 1:1 to either HoLEP or bipolar TUVP using the Gyrus PK device with the Axipolaire electrode. In their study, HoLEP performed better than TUVP with regard to mean operative times (43.6 minutes vs. 60.5 minutes, $P < 0.05$) and fewer patients in the HoLEP arm required bladder irrigation (5% vs. 35%, $P < 0.001$). The other outcomes analyzed, including hospital stay, catheterization time, complication rate, changes in IPSS, and maximum flow rate at 12-month follow-up, were all similar between the two groups. These authors concluded that bipolar TUVP has equivalent functional outcomes to HoLEP but increased intraoperative bleeding, which results in longer operative times and increased postoperative irrigation requirement. Surgeon preference, bias, and familiarity also play a large role and may have influenced these investigators to those conclusions.

## Button-type bipolar plasma vaporization

After introducing Gyrus plasma cutting system in clinical practice, bipolar technology, especially transurethral vaporization of prostate, became a common surgery for prostate resection [7, 15]. For bladder outlet obstruction, bipolar technology is as efficient as transurethral resection and has better long-term prognosis and fewer early complications [16]. This technology has made new progress recently with the utilization of the Olympus UES-40 high-frequency electric generator and “button-type” electrode vaporization resection in transurethral plasma vaporization of prostate in clinical practice. Reich et al. first reported the button-type electrode in the literature [7]. Plasma kinetic button vaporization of the prostate is an endoscopic approach which can be used as an alternative to monopolar TURP. The plasma kinetic technology uses RF energy to create an ionized plasma corona [17] using an axipolar electrode and electroconductive solution such as normal saline [1]. The axipolar vaporesection electrode is in the shape of a mushroom or the so-called “button.” It uses an RF range of 320–450 kHz, a voltage range of 350–450 V, and has a 200 W capability [16, 18]. The current passing over the ball-shaped button creates a plasma corona that vaporizes tissue while achieving hemostasis [19]. Since the axipolar electrode functions as both the working element and the return electrode, the risk of accidental skin burns is eliminated. This also provides decreased interference with cardiac pacemakers and decreased risk of stray currents causing an obturator reflex. Since normal saline is used as irrigation the risk of TUR syndrome is reduced. In bipolar plasma vaporization of the prostate with button electrode, bipolar energy is applied to the tissue using a button-type electrode that vaporizes the prostatic tissue without cutting prostatic fragments.

Button electrodes can work under a higher power because of their capacity for vaporization and strong coagulation. In large prostates, simple bipolar vaporization can be effective for nucleating large quantities of BPH tissue, therefore the button-type electrode, which has a larger contacting surface, was introduced as a novel endoscopic approach [18].

### Equipment and surgery technique

Button-type bipolar plasma vaporization (BTPV) systems require a UES-40 SurgMaster bipolar high-frequency generator, a 26 Fr continuous flow resectoscope, normal saline as irrigant at room temperature, and the aforementioned electrode (Figure 152.4). When the electrode surface is in direct contact with the prostate tissue, the spherical electrode shows a plasma corona. For effective system activation the power output is set at 280–320 W for vaporization (it can be adjusted depending on the tissue) and 120–140 W for coagulation modes. The vaporization technique is performed using the electrode in a near-contact technique (“hovering technique”). In other respects the procedure is performed like a traditional TURP, making the learning curve minimal.

### Clinical experience

In first clinical study, 30 patients with BPH underwent BTPV using the mushroom-like electrode [7]. The mean prostate volume was 59 ml (range 30–170 ml) and mean operative time was 61 minutes (range 20–140 minutes). No perioperative complications were noted, no patient required a blood transfusion, and no postoperative electrolyte abnormalities were noted. Postoperatively, four

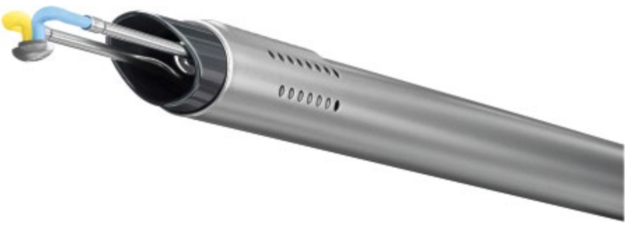

**Figure 152.4** Bipolar mushroom-like electrode. *Source:* Olympus America Inc. Reproduced with permission of Olympus.

patients (13%) required recatheterizations and the mean catheterization time was 41 hours (range 18–192 hours). Around half of the patients (53%) required continuous bladder irrigation postoperatively. The reoperation rate at six months follow-up was 3% (one patient required traditional TURP due to persistent obstructive symptoms). Transient mild-to-moderate dysuria was present in four patients (13%) and resolved within two weeks postoperatively with anti-inflammatory agents. Functional outcomes assessed at six months compared to baseline were excellent. Mean $Q_{\max}$ increased from 6.6 ml/s at baseline to 18.1 ml/s at six months ($P < 0.01$); mean IPSS decreased from 20.8 at baseline to 8.1 at six months ($P < 0.01$); and mean PVR decreased from 165 ml at baseline to 38 ml at six months ($P < 0.01$).

In another study 50 patients underwent prostate surgery by plasma kinetic button vaporization. The median preoperative PSA value was 2.98 ng/ml (0.3–7 ng/ml), median IPSS 22.8 (12–30), median $Q_{\max}$ 6.29 ml/s (3–14 ml/s), and median prostate weight 50 g (20–70 g). No perioperative complications were noted, no patient required a blood transfusion, and no postoperative electrolyte abnormalities were noted. Continuous bladder irrigation was <24 hours in 5 (10%) patients, between 24 and 36 hours in 40 (80%) patients, and >36 hours in 5 patients. Catheterization time was <36 hours in 38 (76%) patients, between 36 and 48 hours in 10 (20%) patients, and >48 hours in 2 (4%) patients. The length of stay was <48 hours in 44 (88%) patients, and between 48 and 72 hours in 6 (12%) patients. In 7 hospitalized patients, acute urinary retention with hematuria and clots was observed, but only in 1 case (2%) was a "second look" endoscopic hemostatic procedure performed. After catheter removal, 3 (6%) patients showed acute urinary retention before discharge and another 3 required rehospitalization for the same problem with the placement of a new catheter. Functional outcomes were assessed at 3, 6, and 12 months; patients showed a significant improvement in $Q_{\max}$ (19.3 ± 5.6 ml/s, 20.3 ± 4.6 ml/s, and 21.2 ± 3.6 ml/s, respectively) ($P < 0.001$). After 12 months, 39 (84.7%) patients had an IPSS <12 ($P < 0.05$). Before surgery, 56% of patients had a QOL >3 and 90% of patients with PVR >50 ml; after 12 months, this result was stable with a QOL >3 in 0% ($P < 0.05$) and a PVR >50 ml in 4.3% ($P < 0.05$). No patient after the procedure experienced incontinence [20].

## Comparative studies

Wroclawski et al. conducted a systematic review and meta-analysis of randomized prospective studies to determine the effectiveness and morbidity of BTPV in comparison with standard transurethral resection (five monopolar and one bipolar) [16, 18, 21–25]. According to this review the mean preoperative IPSS was similar between both groups and both treatments similarly significantly improved symptoms and postoperative IPSS. The need for retreatment due to symptom continuation was mentioned with 6 and 31 events in patients undergoing BTPV and TURP, respectively. Blood transfusion was necessary in two BTPV cases (0.006%) and in 16 TURP cases (0.032%). The mean duration of catheterization was significantly lower in the BTPV group (2.7 days) versus the TURP group (3.9 days). Urethral stricture was mentioned in 13 cases in the BTPV group and in 37 cases in the TURP group. Urinary incontinence was mentioned in 1 case with BTPV and in 6 cases with TURP. The retreatment rates were 3.5%, 9.4%, and 8.8% for BTPV, bipolar TURP, and monopolar TURP, respectively.

Geavlete et al. reported a single-center prospective randomized controlled study on 320 patients in 2015. They randomized the patients with BPH into four groups: bipolar TURP (B-TURP) ($n = 80$), bipolar electrovaporization of the prostate (TUVP) ($n = 80$), BTPV ($n = 80$), and open prostatectomy (OP) ($n = 80$). In terms of preoperative outcomes, there was no difference in age (67.5–69.5 years), prostate volume (122–129 ml), $Q_{\max}$ (6–7 ml/s), IPSS (24–25), PVR (134–158 ml), PSA (7.6–8.2 ng/ml), and QOL scores (4–4.4). According to perioperative outcomes, mean operation time was significantly shorter in the BTPV and OP groups (100 minutes, 118 minutes, 87 minutes, and 80 minutes, respectively). Mean resected adenoma weight was significantly higher in the BTPV and OP groups (78 g, 0 g, 99 g, and 110 g respectively). TUVP was characterized by the lowest mean hemoglobin level drop, followed by B-TURP and BTPV (1.7 g/dl, 0.9 g/dl, 1.6 g/dl, and 3.1 g/dl, respectively). The transvesical prostatectomy group displayed the longest mean catheterization period and hospital stay, next followed by B-TURP, BTPV, and TUVP (2.2–3.2 days, 1.3–2.1 days, 1.6–2.5 days, and 5.4–6.7 days, respectively). During the 1-year evaluation period, statistically similar outcomes were found in all study groups at the checkups at 1, 3, 6, and 12 months with regard to mean IPSS, QOL, and PVR features. On the other hand, the TUVP approach was marked by significantly less pronounced $Q_{\max}$ progress (24.9 ml/s, 22.8 ml/s, 25.6 ml/s, and 25.2 ml/s, respectively). But otherwise equivalent functional parameter results were further confirmed by the related ameliorations when compared to the initial assessment. Moreover, significantly lower mean PSA levels were found subsequent to the OP and plasma nucleation procedures in comparison to bipolar resection and eventually to plasma vaporization (2.01 ng/ml, 3.11 ng/ml, 0.68 ng/ml, 0.69 ng/ml, respectively). As far as the medium-term complications were concerned (encountered between months 1 and 12 of the follow-up period), equivalent data were established regarding the rates of bladder neck sclerosis and urethral strictures (diagnosed by flexible cystoscopy), as well as urinary incontinence [26].

Zhang et al. compared BTPV versus PlasmaKinetic resection of the prostate with a cutting loop electrode for benign prostate enlargement bigger than 90 ml. There was no statistically significant difference in any baseline characteristic of patients (age, prostate volume, PVR, IPSS, and QOL) between the two groups. Significant differences favoring BTPV were found in operation time (64 minutes and 78 minutes), hemoglobin loss (1.18 g/dl and 1.63 g/dl), serum sodium decrease (2.9 mmol/1 and 4.3 mmol/1), the duration of catheterization (49.3 hours and 78.1 hours), and hospital stay (100.2 hours and 116.2 hours). There were no significant differences in IPSS, QOL, and $Q_{\max}$, and PVR in PVEP compared with PlasmaKinetic resection of the prostate at three-month follow-up [27].

When we compare other complications, in a prospective randomized trial Geavlete et al. found monopolar TURP to have a greater number of capsular perforations (7 of 80 monopolar TURP vs. 1 of 75 BTPV, $P = 0.037$). They also reported clot retention occurred significantly less in BTPV compared to monopolar TURP (1 BTPV vs. 7 monopolar TURP, $P = 0.042$) [16]. Although not statistically significant findings, postoperative complications of urinary tract infections and urge incontinence were seen in fewer patients in the BTPV group in all studies. It also appears that the incidence of erectile dysfunction in both procedures is similar (13% BTPV vs. 12% monopolar TURP) [19]. There were higher rates of dysuria and urinary frequency in BTPV compared to monopolar TURP, although neither was found to be statistically significant in any of the trials [17].

Ozturk used BTPV in the treatment of recurrent vesicoureteral anastomotic stricture following retropubic radical prostatectomy. After 24 months follow-up they reported a success rate 89.2% (25 of 28 patients) for this surgery [28].

## Conclusions

Bipolar TUVP has been shown to be a safe and effective treatment for BPH through several well-performed randomized prospective clinical trials. Clearly, larger multicenter trials are needed with longer term follow-up to assess long-term outcomes, specifically the reoperation rate and rate of urethral stricture occurrence. Certainly there is a role for bipolar TUVP in the toolbox of treatments available for BPH as urologists tackle larger prostate glands endoscopically and operate on sicker patients. Whether bipolar TUVP becomes widely accepted remains to be determined, especially in the face of stiff competition from high-powered lasers (holmium and KTP).

## Introduction

The prostate is a pelvic organ with two main pathologies: benign hyperplasia and cancer. These conditions have been more frequently diagnosed in the past 50 years, and there have been significant advances in the surgical management of prostate pathology.

With the introduction of minimally invasive surgery and the development of modern and novel techniques, there has been continued progress over time from the standard use of trocars, through mini-laparoscopy, to single-port robotic surgery. The search for perfect results, not only cosmetically, but also in terms of reducing the morbidity of the procedures, has manifested itself in the reduction in the number and size of trocars.

Single-port surgery globally has continued to evolve and progress with effective and safe results. These advances by surgeons experienced in laparoscopy and robotics have kept the risk of complications low and helped to set strict criteria for the selection of patients appropriate for this surgical approach, while demonstrating, according to some experts, better postoperative pain control, earlier recovery of intestinal function, and smaller scar length than is achieved with standard techniques [1, 2].

## Access, instruments, and viewing

Technical difficulties that may be identified during single-port minimally invasive surgery include: reduced working space, collision of instruments, restricted movements, and difficulty in the display. However, there have been significant improvements and evolution in four important aspects of this surgical approach: trocars, instruments, optical, and mechanism of retraction [3].

## Simple prostatectomy by single port

Currently, despite advances in endoscopic techniques with the application of new technologies (e.g. bipolar transurethral resection, holmium laser resection, and potassium titanyl phosphate (KTP) laser vaporization) and the emergence of new access devices, open surgery is considered the standard management for prostates of large size in terms of cost-effectiveness for benign hyperplasia.

Over the last decade, with the advent of laparoscopic and robotic surgery, new treatment alternatives have been developed and implemented. In 2002, Mariano et al. described a technique for simple laparoscopic prostatectomy [4], which was reproduced with some modifications and then performed with robotic assistance. The described surgery essentially duplicated the techniques of open surgery, while maintaining a comparable proportion of prostatic tissue extracted as in open surgery, but with the benefits associated with minimally invasive surgery [5, 6].

With the aim of improving cosmetic results and maintaining the good surgical outcomes of laparoscopy, the use of a single point of access into the abdominal cavity through the umbilicus was implemented. This approach was named laparoendoscopic single-site (LESS) surgery, which is the use of endoscopic and laparoscopic techniques through a single hole, using a unique device that enables the introduction of several instruments [7]. We began to explore the possibilities of applying this

*Smith's Textbook of Endourology*, Fourth Edition. Edited by Arthur D. Smith, Glenn M. Preminger, Louis R. Kavoussi, and Gopal H. Badlani.

new access method to our technique of laparoscopic simple prostatectomy, initially through the umbilicus and later through a small suprapubic incision to place the port directly into the bladder.

## Single-port transvesical enucleation of the prostate

LESS adenomectomy can be performed by placing a single-port device through the umbilicus using a transperitoneal approach. This is challenging, because the bladder must be dropped and the finger cannot be used to assist with enucleation of the prostate adenoma. In addition, at the end of surgery, the bladder incision must be closed laparoscopically in a watertight manner. With the introduction of the new double-bend instruments, this step has become easier, but can still be technically difficult to complete.

Another option is to place the port directly through the bladder (Figure 153.1). With this approach, the bladder does not need to be dropped, and the finger can be used to assist with the enucleation. At the end of surgery, the bladder closure can be done in a standard open fashion.

Laparoendoscopic transvesical simple prostatectomy is performed through a small incision approximately 2.5–3 cm long, located 3 cm above the pubic symphysis, through which a specialized access device is directly inserted. Through this single access point, multiple instruments can be inserted to complete the operation. The R-port® (Advanced Surgical Concepts, Wicklow, Ireland) was the initial design of this access device, and modifications have led to the development of the TriPort® and QuadPort® (Advanced Surgical Concepts), which each have three and four channels, respectively. This device has two important features: first, it has multiple flexible valves that do not protrude into the cavity and enable the introduction of curved instruments; and second, it has a valve component that is easy to open and does not need to be taken out to be changed – a crucial aspect in intraluminal surgery. Increasing interest in LESS surgery has led to the introduction of new instruments, such as the 5 mm flexible EndoEye videoscope (Olympus, Tokyo, Japan), which provides excellent optics and images, and flexible, curved instruments that permit dissection and laparoscopic intracorporeal suturing [8].

The approach to the surgical management of urinary tract obstructive symptoms secondary to benign growth of the prostate is selected according to the technique used, size of the prostate, and the ability of the surgeon.

### Technique

Current surgical approaches used include endoscopic techniques, such as transurethral resection of the prostate (TURP) (main standard), new trends with laser technology (enucleation with a holmium laser (HoLEP), laser green, among others), open surgery, and laparoscopic and robotic surgery [9].

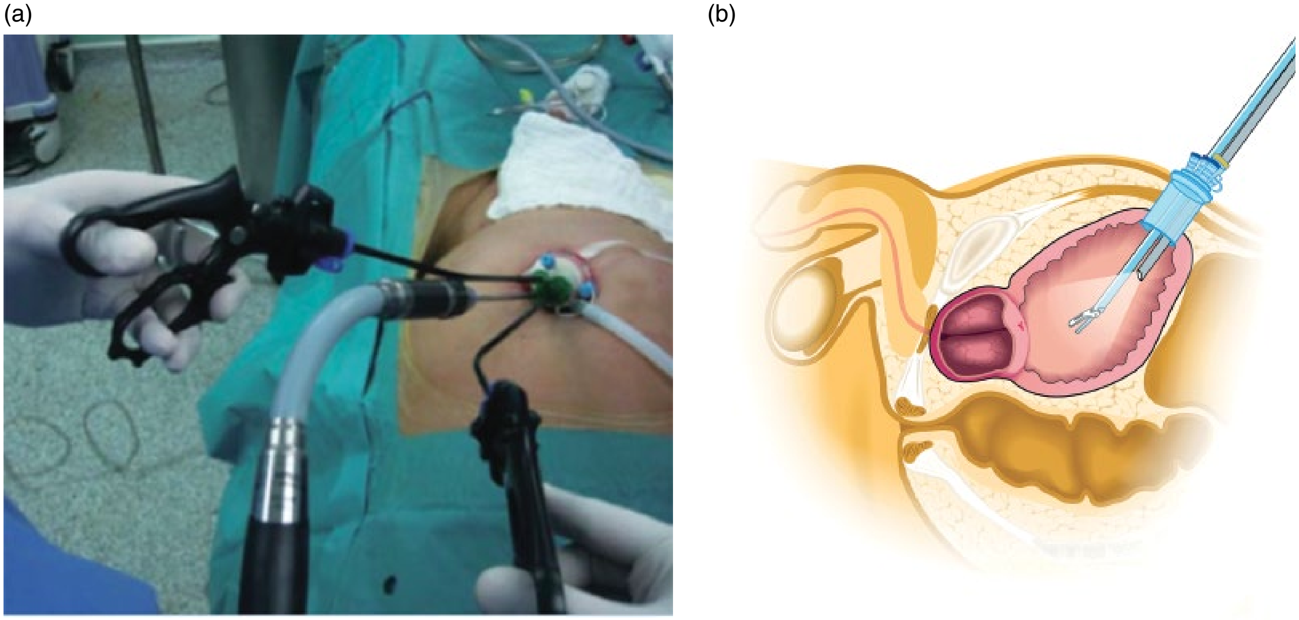

**Figure 153.1** (a, b). Port placement directly through the bladder. Insertion and deployment of the TriPort under cystoscopic guidance.

## Size

Surgery on prostates of less than 80 g should be performed using endoscopic techniques, although there are reports of prostates of larger size (≥120 g) being managed this way. For prostates ≥80 g, open, laparoscopic, and robotic surgery have traditionally been the recommended approaches.

## Ability of the surgeon

The surgeon must resect the greatest amount of tissue in the shortest time possible to avoid complications such as bleeding, irritative symptoms, and postresection syndrome. It is reported that expert hands can achieve a resection rate of 1–1.5 g/min.

Laparoscopic robotic surgery can duplicate the open surgery technique, and demonstrates the same surgical outcomes. It is safe and effective, with less blood loss and a shorter length of hospitalization. It may, however, have a longer operative time. Comparisons of laparoscopic and endoscopic surgery show that the former has the highest percentage of tissue resection and shorter use of a bladder catheter, at the expense of greater bleeding [10, 11].

Simple prostatectomy by single port was initially described in 2008 by Desai et al. [8]. An early experience in three patients with large prostates involved use of the R-port device, which was introduced percutaneously into the bladder through a 2.5 cm infra-umbilical incision under the guidance of cystoscopy (with prior introduction of a hypodermic needle), followed by a U-shaped incision into the bladder neck and adenoma dissection. This direct bladder approach allowed the dissection of the adenoma to be made with assistance of the surgeon's finger, in addition to the apparent advantage of not needing to close the bladder [8]. Sotelo and his group also detailed their technique of simple prostatectomy in 2009 using a multilumen single port through an umbilical incision of 2.5 cm. They described difficulty in developing the prevesical space and subsequent bladder dissection, and after making the cystotomy, had to complete the dissection of the adenoma without the use of additional trocars or percutaneous traction maneuvers [12]. These two groups of researchers have together presented a multi-institutional series of large-scale single-port simple prostatectomies.

## Surgical technique

The equipment and instruments required for single-port transvesical enucleation are listed in Box 153.1. The TriPort is a multiport access device that allows several instruments to pass through simultaneously. It consists of a retractor and a valve. The Choker has an inner ring, two outer rings, and a retractable plastic sleeve. The valve has three openings (two of 5 mm and one of 12 mm) for laparoscopic instruments and a port for inflation. The valve contains a thermoplastic elastomer that enables the proper introduction of the instruments, including needles, with insignificant air loss.

## Surgical steps

The advantages and disadvantages of this procedure are summarized in Box 153.2 and the key points in Box 153.3.

### Patient position and endoscopic evaluation

All procedures are performed under general anesthesia with the patient in a modified low lithotomy position.

**Box 153.1 Equipment and instruments required for single-port transvesical simple prostatectomy.**

**Equipment**

- Laparoscopic video tower (21-inch monitor, EXERA II image processor with light source)
- Video laparoscope: EndoEye (Olympus, Tokyo, Japan), 5 mm, 30° lens
- UHI-3 high-flow $CO_2$ inflator (up to 35 l/min)
- Ultrasonic generator
- Electrosurgical unit (monopolar/bipolar)
- Aspiration–irrigation pump
- Flexible cystoscope

**Instruments to develop the procedure**

- TriPort (Advanced Surgical Concepts, Wicklow, Ireland/Olympus)
- 5 mm flexible articulating instruments: scissors (Cambridge Endo, Framingham, MA, USA)
- 5 mm J hook electrocautery instrument
- Ultrasonic 5 mm shears
- 5 mm suction–irrigation cannula, prebent
- Carter–Thomason device
- Two laparoscopic needle holders
- Silicone three-way 22 Fr and two-way 24 Fr Foley catheters, in case a suprapubic tube is needed
- Sutures: Monocryl 0 with CT-1 needle for adenoma traction, and 2/0 with CT-1 needle for ligature of lateral pedicles and trigonization (the monofilament facilitates the extra-corporeal knotting)
- Sotelo prostatotomy device
- Knot pushers

**Box 153.2 Advantages and disadvantages of single-port transvesical simple prostatectomy.**

**Advantages**

- Pneumovesicum maintains a broad field of work
- Allows the observation of all anatomic details of the bladder, prostate and urethra during each step of the surgery
- Lower risk of intestinal injury and lower likelihood of development of postoperative ileus
- Easy opening of the device enables the extraction of fragments during surgery. Furthermore, it allows the introduction of a finger if necessary to remove the adenoma
- Due to the fact that the adenoma fragments are confined in the bladder and are not released in the abdominal cavity, extraction pouches are not necessary

**Disadvantages**

- Steep learning curve. At first, enucleation is difficult, but the location of the suprapubic incision allows bimanual dissection if necessary. The index finger of the left hand in the rectum elevates the prostatic fossa and the index finger of the right hand through the ring of the TriPort helps the mobilization of the adenoma

**Box 153.3 Key points during the procedure.**

- Placement of a traction suture through the full thickness of the bladder using absorbable material. The same stitch will enable placement of subsequent stitches, which will facilitate introduction of the trocar and the closure of the defect at the end of the case.
- It is important to lubricate the entrance of the TriPort in order to facilitate entry of instruments through the membranes, as well as facilitating the introduction of the videoscope and its rotational movement.
- The incision should be made between the adenoma and the mucosa of the bladder. The surgeon can observe a faint change in color. This serves as a reassuring reference point.
- If problems arise in the traction of the adenoma, the suture can be exteriorized through the abdominal wall with the assistance of a Carter–Thomason device.
- A useful tool designed specifically for prostatic adenomectomy is the Sotelo prostatotomy device. This consists of three parts: a Teflon sleeve, a stainless-steel cylinder body, and a curved shape with sharp edges at the distal end.
- It is important to note that, if necessary, the surgeon can convert the procedure to a standard laparoscopic surgery with the addition of more trocars as necessary.

Initially, cystoscopy is performed and the prostate evaluated endoscopically. The bladder is filled with normal saline solution.

### Insertion and deployment of the TriPort

An approximately 2.5 cm skin incision is carried down to the rectus fascia. The incision is located just above the pubis. The bladder wall is identified and cleared of any prevesical fat. Two stay sutures of 2-0 Vicryl are placed.

The bladder wall is entered sharply between the stay sutures, and the inner ring of the TriPort is inserted into the bladder and deployed with the help of an introducer. The inner and outer rings are approximated by removing the slack on the plastic sleeve, thereby cinching the abdominal and bladder walls between the rings of the TriPort in an airtight seal. The valve of the TriPort is inserted and the bladder insufflated with $CO_2$ to create the pneumovesicum. The insertion and deployment of the TriPort is monitored cystoscopically (Figure 153.2).

The use of absorbable material for stitches in the bladder is important. These pass through its entire thickness, one in front of the other. The stitches serve as the anchor for traction and also facilitate the introduction of the trocar. They are also tied together to close the defect upon completion of the surgery. Care must be taken that the incision in the fascia and the bladder is no more than 2.5 cm, otherwise the inner ring of the TriPort will be dislodged. In Figure 153.2, the inner ring of the TriPort is seen outside of the bladder.

### Mucosal incision and enucleation

A large, bulging median lobe can be retracted anteriorly in an efficacious manner with a figure-of-eight stay stitch. This can be placed with a Keith needle or Carter–Thomason port closure needle device. The two ends of the stay stitch are retrieved and anchored outside of the anterior abdominal wall. A Monocryl suture on a CT-1 needle is placed through the adenoma for retraction purposes (Figure 153.3a). A U-shaped incision is made over the bladder mucosa, immediately overlying the adenoma, from the 3 o'clock to the 9 o'clock position, and through the 6 o'clock position. Typically, a reddish zone of mucosa is seen immediately lateral to the internal meatus. This serves as a reliable guide for creating the mucosal incision. The horizontal limb of the U-incision is made using a hook electrode and cutting current to reach the adenoma. The whitish prostatic adenoma is readily identified. The plane between the surgical capsule and the adenoma is created using a hook and suction cannula. The two limbs of the U-incision are created, followed by completion of the circumferential mucosal incision (Figure 153.3b). Separate excisions of each mobilized lobe of the adenoma provide superior visualization of the remaining part of the adenoma, enabling better hemostasis.

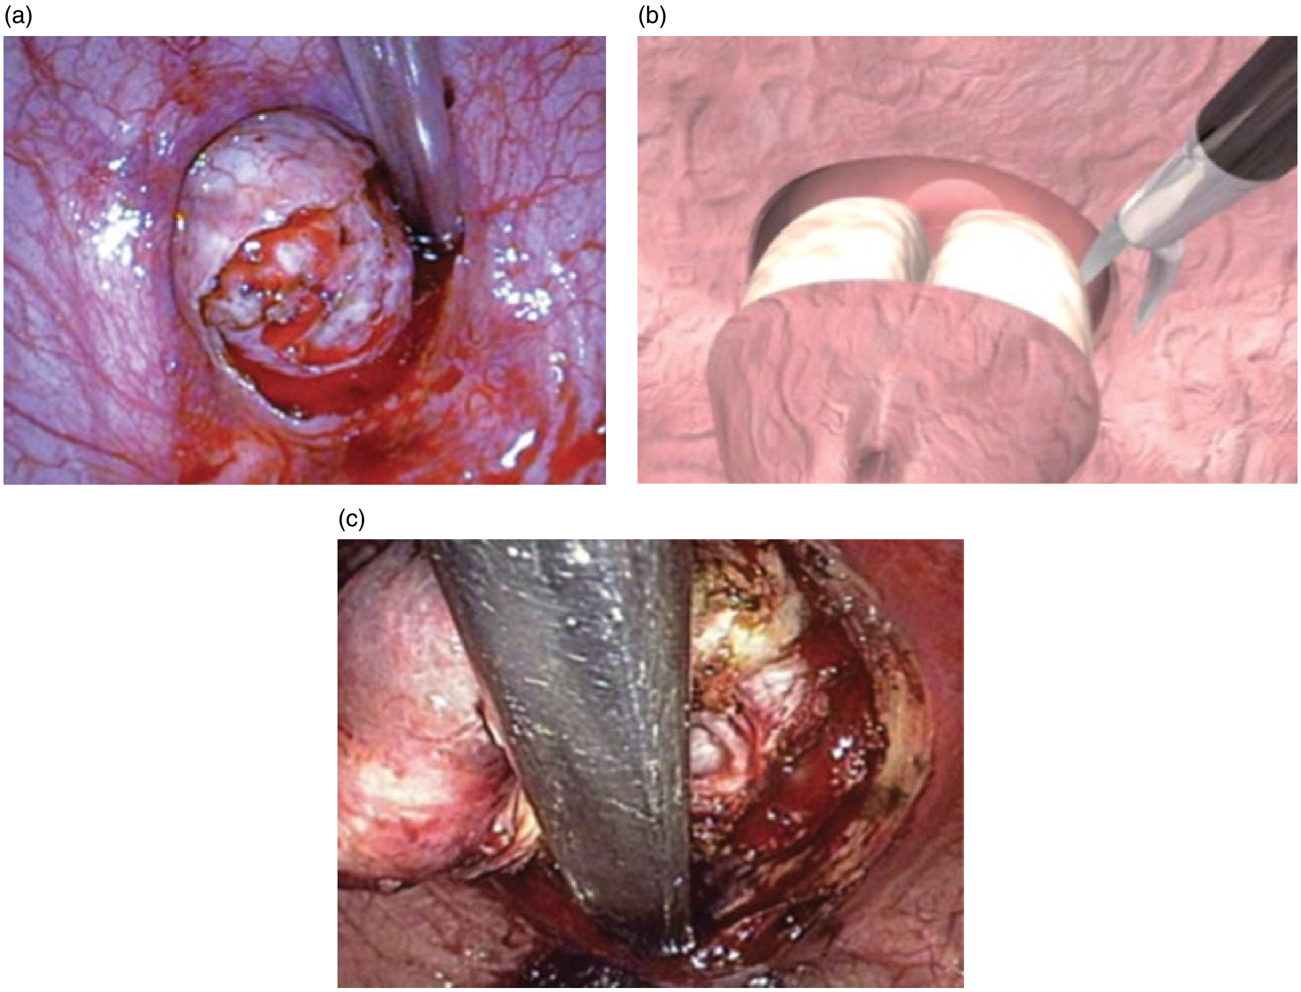

**Figure 153.3** (a) A Monocryl suture on a CT-1 needle is placed through the adenoma for retraction. (b) Mucosal incision and enucleation. (c) Division of prostatic adhesions.

Several maneuvers are used to facilitate the enucleation of the adenoma:

- The valve is removed first and then the right index finger is inserted through the TriPort. This expedites the distal part of the enucleation. The left index finger is placed into the rectum to elevate the prostate. Once the finger dissection has been completed, the TriPort valve is reattached. The pneumovesicum is re-established for incising the urethra at the prostatic apex and completing the procedure.
- Use of the "Sotelo prostatotomy," a device similar to a curette or an osteotome, facilitates enucleation of the adenoma during laparoscopic simple prostatectomy. Its metallic curvilinear tip, with a sharp cold knife on the distal side of the forceps, is used to divide the adhesions between the adenoma and its capsule during circumferential dissection of the gland (Figure 153.3c).
- The urethra is incised with a bipolar resectoscope through the urethra, immediately after the placement of the port and before any dissection from above (Figure 153.4).

#### Hemostasis

After removing the adenoma, hemostatic figure-of-eight sutures are tied down with an extracorporeal knot pusher and must be placed at the 4 and 8 o'clock positions at the prostatic capsule, to control the main prostatic vessels (Figure 153.5).

The lateral pedicles of the prostate should be thoroughly checked and the pneumovesicum pressure decreased to ensure that there is no bleeding. In the event that there is slight bleeding, it can be controlled with a monopolar or bipolar unit. If there is still any doubt, stitches can be made with absorbable sutures and knotted extracorporeally.

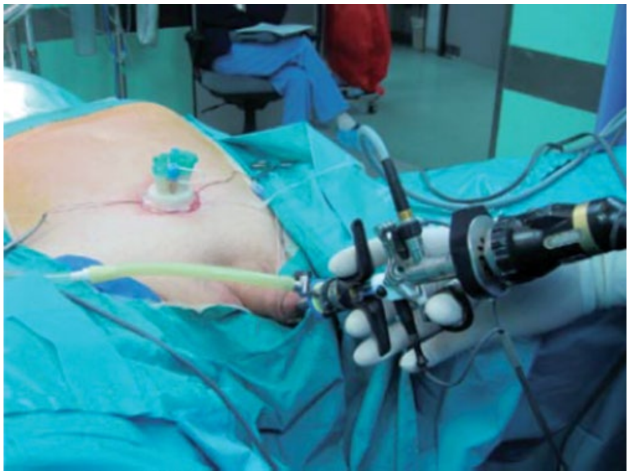

**Figure 153.4** Incision of the urethra with a bipolar resectoscope.

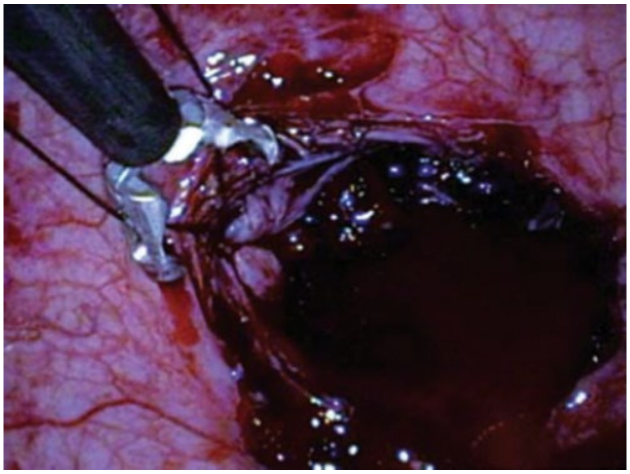

**Figure 153.5** Hemostasis of the main prostatic vessels with figure-of-eight sutures. These are tied down with an extracorporeal knot pusher and must be placed at the 4 and 8 o'clock positions of the prostatic capsule.

#### Specimen extraction

The prostatic adenoma is extracted through the TriPort ring after dividing it into multiple pieces during extraction with Allis forceps (Figure 153.6).

#### Trigonization and closure of the bladder

After removal of the adenoma, trigonization of the prostatic fossa can be performed by suturing the cut end of the posterior bladder neck distally toward the apex of the prostatic fossa. This can be tied down with an extracorporeal knot pusher.

The bladder opening is sutured with 3-0 Vicryl, and the fascia and skin are closed in a standard fashion. Depending on the amount of bleeding, a suprapubic catheter can be inserted through the inner ring of the TriPort (Figure 153.7). The balloon should be inflated before the TriPort is removed. The ring of the TriPort is large enough to pass the distal part of the catheter. In this way, it is easier to ensure that the Foley catheter is inside the bladder (Figure 153.8). Thus, the first Vicryl stay suture, which was previously placed in the bladder, can be tied, along with any additional sutures, to give a watertight closure.

The interest of urologists in single-port surgery has been maintained. When LESS surgery is performed by experienced surgeons, it is considered safe, with rates of conversion and complications similar to those obtained through laparoscopic multiport access (Table 153.1).

Simple prostatectomy by single-port laparoscopy outcomes have been reviewed through large multi-institutional studies at centers where surgeons have greater experience in this technique. These larger studies have strengthened statistics and provided points in favor of re-evaluating at each surgery. Simple prostatectomy by single port is a technically challenging procedure, and for

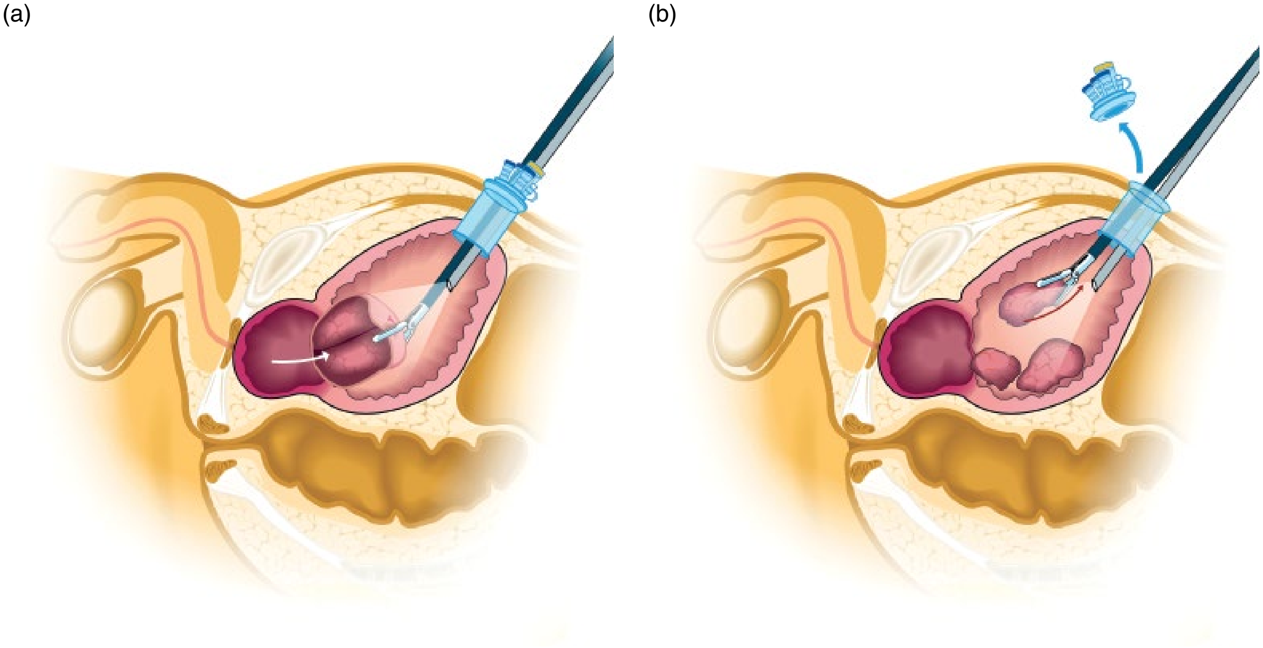

**Figure 153.6** (a, b). Prostatic adenoma is extracted through the TriPort ring after dividing it into multiple pieces during extraction with the Allis forceps.

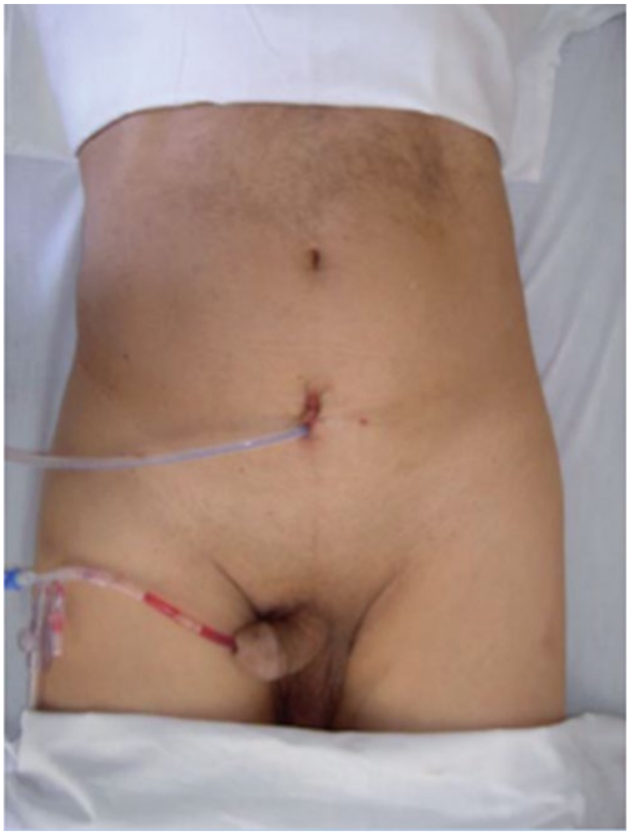

**Figure 153.7** Insertion of a suprapubic catheter through the inner ring of the TriPort.

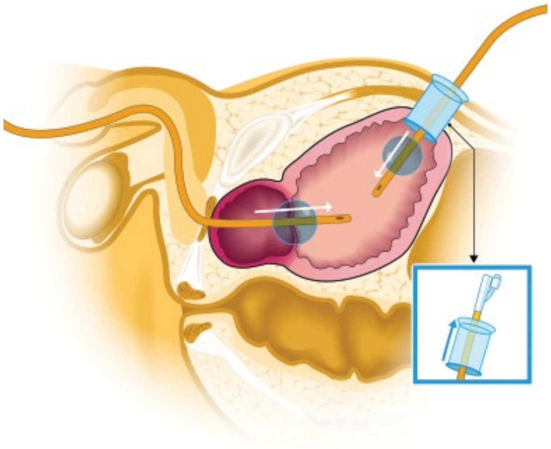

**Figure 153.8** The ring of the TriPort is large enough to pass the distal part of the catheter. This is the easiest way to ensure the Foley catheter is inside the bladder.

this reason it is thought that it will have little relevance and applicability in the future in urology [17]. However, it should be noted, that this technique has been used as the basis for the next generation of pelvic surgery, "radical prostatectomy by single port," which has great potential in the future of global urology.

## Single-port radical prostatectomy by laparoscopy

### Transumbilical approach

In 2008, the first single-port radical prostatectomy by laparoscopy (laparoendoscopic single-site radical prostatectomy, LESS-RP) was carried out in four patients with low-risk prostate cancer. A transabdominal approach was used, with a Uni-X port (Pnavel Systems, Morganville, NJ, USA) (Figure 153.9). The greatest difficulty described by Kaouk et al. occurred with the urethrovesical anastomosis, which was only achieved with suture interrupted with exo-nudos (knots tied on the outside, with a knot pusher). The use of an additional port was not necessary in any of these cases. One complication reported was of a patient who suffered a rectourethral fistula (Clavien grade IIIb), which was resolved with surgical management. From an oncologic viewpoint, half of the patients (2) had positive surgical margins with a detectable prostate specific antigen (PSA) at follow-up, and no reports of erectile function [18]. In another series of 31 cases in 2012, looking at nerve sparing in low-risk tumors (T1c to T2a) and presurgical Sexual Health Infentory for Men (SHIM) score >21, an additional 3.5 mm port was used [19]. These authors reported 32.3% nerve sparing, and 33% of the patients maintained adequate erectile function in the postoperative period (SHIM score in this series >21 points with or without medication).

The main approach used currently for LESS-RP is transperitoneal; however, an extraperitoneal approach has been described. In their first experience, Rabenalt et al. used the TriPort (Advanced Surgical Concepts) device and precurving instruments, achieving an anterograde dissection and 6 points apart in anastomoses in each of the cases [20]. Another group that reported their experience with the extraperitoneal approach described the use of two systems: the QuadPort multichannel (Olympus, Japan) and an artisan multichannel device made with a surgical glove, which used a flexible laparoscope and precurved and flexible instruments [21]. The last series reported was in 2013 by Jiang et al., who performed an extraperitoneal approach in 20 patients with a variable artisan multichannel device made with a surgical glove, along with straight and precurved instruments [22]. All describe the advantage of using precurved tools for LESS-RP.

## Transvesical approach

With applying the concept of transvesical simple prostatectomy by single port described by Desai et al. in 2008 [8], in 2011 Gao et al. published the largest series of transvesical prostatectomy by single port in 20 patients with low-risk prostate cancer (PSA = 10 ng/ml, Gleason <7 and clinical stage T1c or T2a). They began the initial dissection with a retrograde approach, starting by the bladder neck, and subsequently worked in an antegrade manner with dissection of the seminal vesicles and prostate; urethrovesical anastomosis was performed by inserting a foreskin graft with separate points. No additional ports were used and the neurovascular package was preserved in all patients, with reported results of 60% erectile function with 21 points or more on the International Index of Erectile Function (IIEF-5) scale, 100% continence, and 0% positive margins. Two years later, another series of 16 patients from the same author was published. This featured the addition of an innovative way to release tension on the anastomosis by making three incisions near the bladder neck, and completing the anastomosis with continuous barbed suture on each side [23] (Figure 153.10).

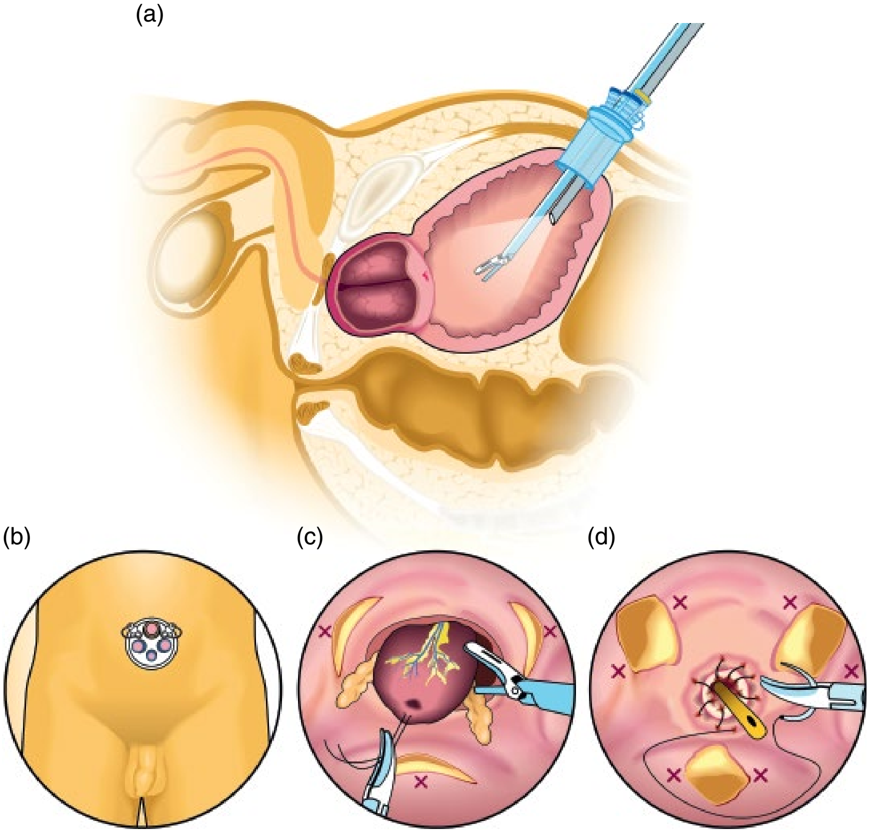

**Figure 153.10** Transvesical laparoendoscopic single-site radical prostatectomy (LESS-RP). (a) Lateral view, (b) umbilical QuadPort, (c) mucosa–muscle incisions between 2 and 4 o'clock, 5 and 7 o'clock, and 8 and 10 o'clock, marked as "X," ease urethra–bladder anastomosis, (d) continuous closure urethra–bladder anastomosis and enlargement of the mucosa–muscle incisions.

## Radical prostatectomy single-port laparoscopy assisted

The well-known advantage of the laparoscopic robot-assisted approach is the mobility of the instruments, which theoretically decreases the likelihood of collision. The da Vinci® (Intuitive Surgical Inc., Sunnyvale, CA, USA) surgical system has been characterized by its size and bulky nature, and it is clear that initial robotic platforms were not developed for LESS procedures. Nevertheless, surgeons and urologists have carried out single-port robot-assisted radical prostatectomies (R-LESS-RP).

### Transumbilical technique

The first two cases of R-LESS-RP were reported by the Montsouris group in 2009. The first case was in a cadaveric model and the second in a living patient [24, 25]. In both cases no single-port device was used, but a single umbilical incision was made with subsequent separate insertion of a trocar; a 12 mm port for the camera was used and two 8 mm robotic ports for the tools with a separation between the ports of approximately 3.5 cm. The dorsal venous complex was closed with a stitch and the urethrovesical anastomosis was performed with six separate points. The main difficulty described by surgeons was the external collision of the robotic arms, with the consequent limitation of movement and progression of surgery. This French technique and its rhomboid configuration of ports has been replicated by other groups trying to make it functional and successful (Figure 153.11).

To date, the most extensive series has been described by White et al. [26], who describe the results of 20 patients undergoing R-LESS-RP. They used two 8 mm robotic ports and one single-incision laparoscopic surgery (SILS) port. The robotic laparoscope was placed through the channel of the SILS, which measured 12 mm. The surgical technical was done in antegrade manner, following the steps of the conventional technique of prostatectomy radically assisted by a robot, with an average operating time of 200 minutes. Out of the 20 patients only 4 had complications. Oncological results revealed positive surgical margins in 24% of the evaluated patients (4/17) and node dissections were carried out in 60% of the patients.

A recent series with 11 patients describes the use of the first prototype of the da Vinci SP® single-port robotics platform, which offers insertion of the camera and instruments through a single port. In general, the patients were young, with a medium prostate, not obese, and of low risk. In this series conversion was reported to be 0% and the complications were mostly minor. The average surgical time was 239 minutes, with 18.2% positive margins, continence to 30 days of 55%, and potency of 63.3% [27].

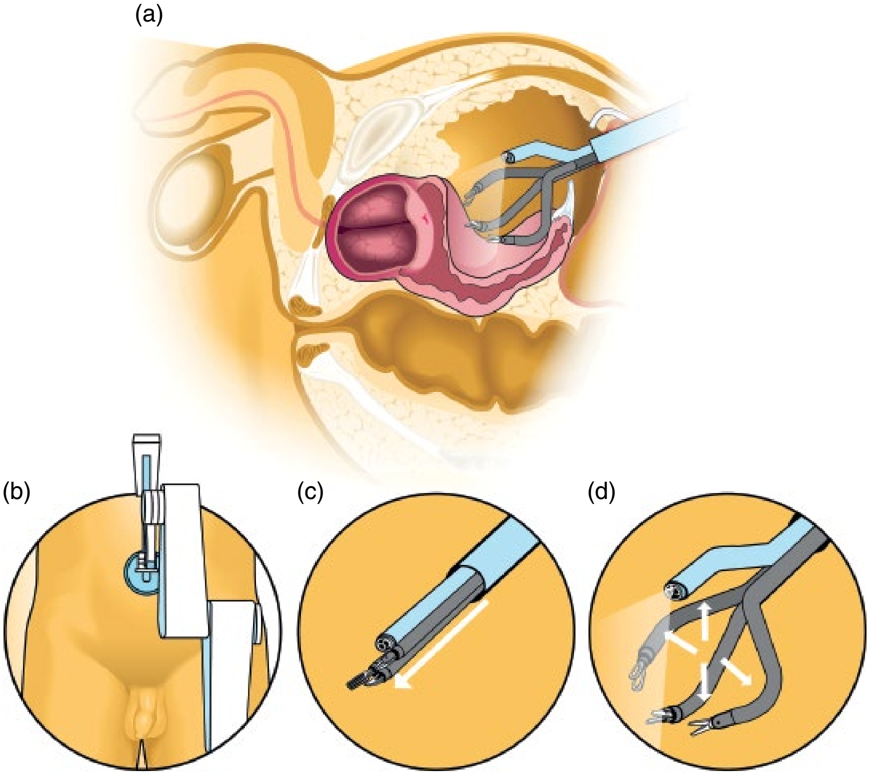

**Figure 153.11** Transperitoneal robot-assisted laparoendoscopic single-site radical prostatectomy (R-LESS-RP). (a) Lateral view, (b) da Vinci SP docking, (c) system elements entry, (d) system components deployment. The "Y" principle is observed.

### Transvesical technique

The first transvesical robotic radical prostatectomy (TRRP) was developed in two cadaveric models in 2008 by Drs. Desai and Sotelo. The first model involves a suprapubic horizontal incision (mini-Pfannenstiel) and includes several trocars through the fascia to the bladder. In the second model a QuadPort system was used. This device showed advantages over the conventional trocars by a single orifice, and from this observation this technique was adapted as a possible way by surgeons to make this intervention [3, 28]. In 2009 they performed the surgery in a 61-year-old patient with prostate cancer while preserving the neurovascular bundles and avoiding the use of additional ports [29] (Figure 153.12).

## The future

The first robotic platform was developed in 2012 and was designed to improve the interface between the surgeon and the patient, to avoid difficulty generating movements in an inverted mirror through a computer on the platform; however, these instruments lacked articulated movement, making some complex movements, such as suturing, more difficult, in addition to collisions of the external arms.

With a completely different concept – a Y-shaped single port – the second single-port robotic platform offered an intracorporeal triangulation with flexible instruments, thereby avoiding any possible collisions. This design is characterized by a straight shaft and two-sided flexible instruments, and a 3D laparoscope with a relatively small and flexible diameter at the tip. The three instruments and optics are introduced through a straight sheath, providing a solid instrument.

This concept of a Y-shaped platform has been used to perfect a new single-port robotic prototype called a "spring plate mechanism," which is characterized by a spring plate that enables the transmission of force and improves the size of the working space.

The da Vinci Single Port (SP) system entered the market in late 2017, after FDA approval, bringing with it the great advantage of being able to perform surgery in a single quadrant with a single incision of 2.5 cm, leading to expectations that it will prove to be a highly successful tool in minimally invasive surgery following its initial promising results [27] (Figure 153.13).

In the field of urology, the first natural orifice transluminal endoscopic surgery (NOTES) procedure described was a transvaginal nephrectomy in a porcine model in 2002. This was followed by a human nephrectomy using a transvaginal port. A pioneer group, Krambeck and

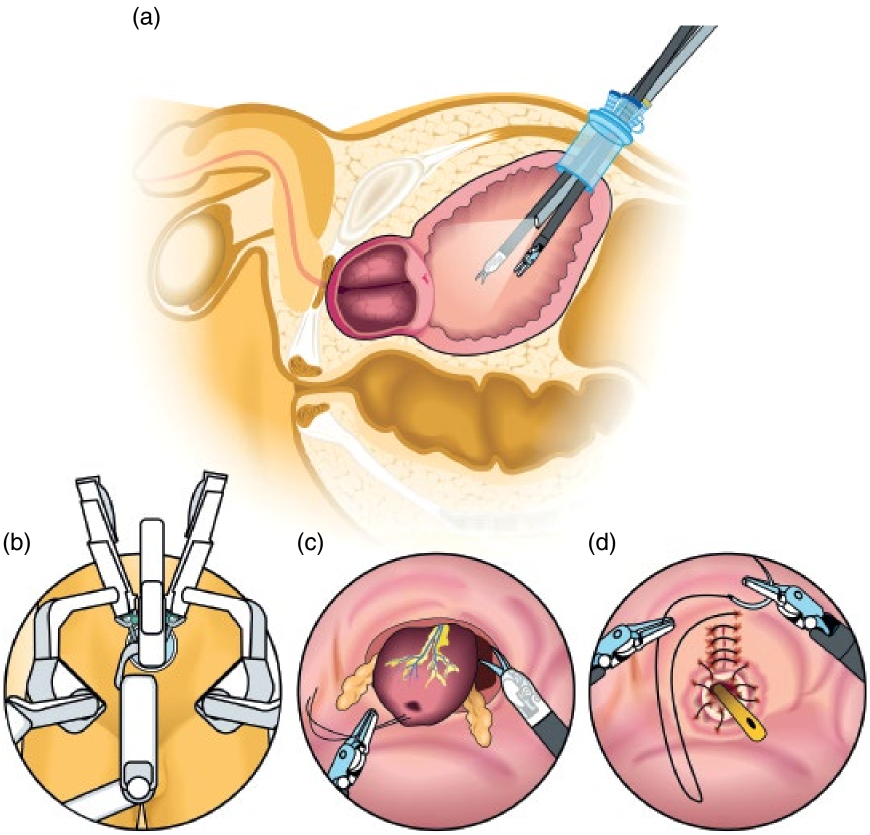

**Figure 153.12** Transperitoneal robot-assisted laparoendoscopic single-site radical prostatectomy (R-LESS-RP). (a) Lateral view, (b) da Vinci Si docking, (c) intravesical dissection of the prostate and seminal vesicles, (d) urethra–bladder anastomosis with anterior plication.

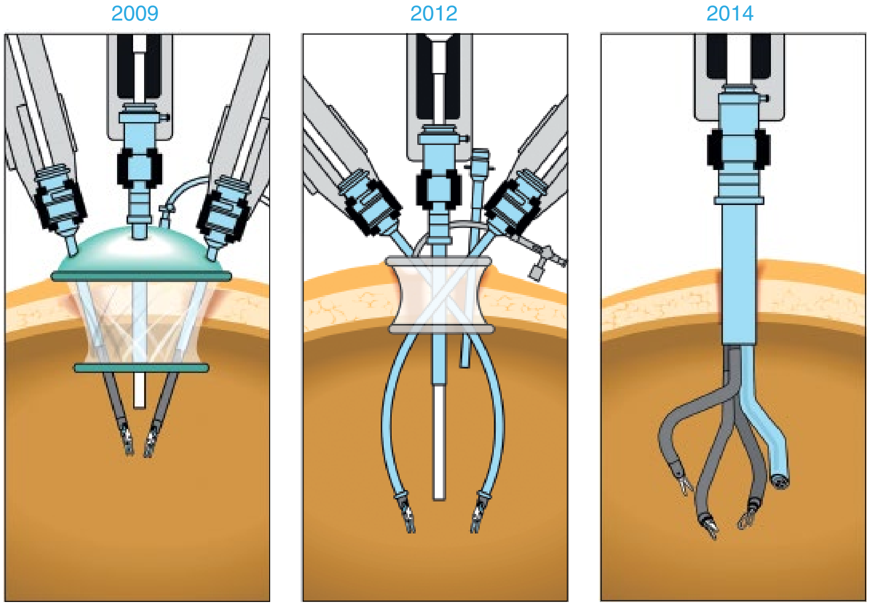

**Figure 153.13** Robotic laparoendoscopic single-site (LESS) prostatectomy: (2009) First radical LESS prostatectomy, rhomboidal configuration; (2012) first platform LESS VesPa (not used for prostate), (2014) second platform LESS, da Vinci SP uses "Y" principle.

Humphreys, demonstrated the feasibility of NOTES-RP (natural orifice transluminal endoscopic surgery – radical prostatectomy) in canine and cadaveric models in 2010 and 2011, respectively, using the urethra as the natural orifice [30, 31]. They used a holmium (Ho:YAG) laser (VersaPulse®, Lumenis Inc., Santa Clara, CA, USA) with a 26 Fr resectoscope to complete the prostate dissection procedure. The prostate sample was liquefied (using a morcellator) and the anastomosis was performed through a urethravesical anastomosis device (LSI Solutions, Victor, NY, USA) with monofilament polydioxanone 3-0.

Laparoscopic surgery depends on visual information since there is a lack of tactile feedback. The RoboSurgeon System® was developed to address this. It incorporates a system with a head-mounted display (HMD) combining a three-dimensional organic electroluminescent HMD unit (HMS-3000MT, Sony Corporation, Tokyo, Japan) with various image modalities, including an endoscope, transrectal ultrasound, and magnetic resonance imaging through interface multiplexers, enabling an improvement in technique and results in real time [32].

These developments demonstrate how quickly surgeons are modifying surgical approaches and designing techniques that are less invasive with the goal of achieving good results.

See accompanying Video 153.1.

## Introduction

Overactive bladder (OAB), as defined by the International Continence Society, is "urinary urgency, usually accompanied by frequency and nocturia, with or without urgency urinary incontinence, in the absence of urinary tract infection (UTI) or other obvious pathology" [1]. OAB can be neurogenic (N-OAB) or idiopathic (I-OAB). N-OAB results directly from neurologic disorders, such as multiple sclerosis, myelomeningocele, and spinal cord injury [2], while I-OAB is a clinical diagnosis of exclusion after ruling out alternative sources of symptoms, such as benign prostatic hyperplasia (BPH), UTI, malignancy, or painful bladder syndrome [3, 4]. The worldwide incidence of OAB is estimated to be 11% [5], and the prevalence ranges from 7% to 27% in men and 9–43% in women [3, 5–12]. The primary concern for many OAB patients is reduced quality of life (QOL) [13–17]. I-OAB leads to deterioration in QOL in about 50% of patients, with the proportion increasing to 80% in those with incontinence [17]. The impact on QOL can extend to sexual function, marital satisfaction, and psychosocial functioning with increased rates of depression associated with worsening incontinence symptoms [18–21].

First-line treatment of OAB includes behavioral therapies combined with pharmacologic management when necessary [3, 4]. Behavioral modifications include bladder training, pelvic muscle training, fluid management, and bladder control strategies. Pharmacotherapy may be initiated simultaneously with behavioral therapy or when behavioral therapy is insufficient in managing symptoms. Pharmacologic options are considered second-line interventions and include anticholinergic/antimuscarinic and beta-adrenergic medications. Cholinergic receptors in the bladder, stimulated by acetylcholine released from parasympathetic neurons, are responsible for bladder contraction during voiding [22, 23]. However, such receptors exist elsewhere in the body, including the brain, salivary glands, heart, gastrointestinal tract, and eyes, resulting in side-effects, such as cognitive problems, dry mouth, tachycardia, constipation, and blurred vision [3, 22, 23]. Such side-effects, along with a relative lack of efficacy, have led to discontinuation of anticholinergic medication in >60% of patients at 12 months [24]. Almost half of patients discontinued medication because they felt it "did not work as expected," and almost one-fourth of patients cited the side-effects as their reason [25]. Mirabegron, a beta-adrenoceptor agonist, is an alternative to anticholinergic medications with similar efficacy for treatment of OAB [26] although currently there are relatively few studies. By targeting the sympathetic system, mirabegron can be used in patients with poor tolerance or contraindications to anticholinergic therapy. Mirabegron has been shown to have lower rates of dry mouth and constipation, which may contribute to higher rates of adherence and persistence at 12 months compared to anticholinergics [27].

Patients refractory to first- and second-line treatments may be offered botulinum toxin A (BTX-A) intravesical injections, peripheral tibial nerve stimulation, or sacral neuromodulation. In rare cases, the patient with refractory OAB may be offered indwelling catheterization or surgery, such as bladder augmentation or urinary diversion. This chapter discusses the mechanism, efficacy, technique, and side-effects of endoscopic injections of BTX-A into the detrusor wall of patients with refractory OAB.

## Mechanism of action

Botulinum toxin is a potent neurotoxin produced by the anaerobic bacterium *Clostridium botulinum*, which can result in severe symptoms including mydriasis and progressive neuromuscular paralysis, producing muscle weakness, dyspnea, and possibly death. These symptoms were first described in the 1820s by the German physician Kerner who observed an outbreak among soldiers suffering "sausage poisoning" from having eaten infected sausages [28]. It was not until 1897 that the microbiologist van Ermengem discovered the culprit bacterium which he termed "bacillus botulinus" (from the Latin word *botulus* meaning sausage) after isolating it from the tissue of several people who died following a funeral dinner as well as from the smoked ham served that day [29]. Botulinum toxin was first used medically in 1977 by the opthalmologist Scott to treat patients with strabismus or blepharospasm, and US Food and Drug Administration (FDA) approval for this application was granted in 1989 [30]. In 1988, Dysktra et al. described the first urologic application of botulinum toxin – injection into the external urinary sphincter to treat detrusor sphincter dyssynergia in spinal cord injury patients [31]. Since that time, the urologic indications for therapy have expanded to include N-OAB, I-OAB, interstitial cystitis/bladder pain syndrome (IC/BPS), chronic pelvic pain syndrome, and detrusor sphincter dyssynergia (DSD).

The pathophysiology of OAB is not fully understood, but may involve lack of inhibition by upper motor neurons in patients with N-OAB, and oversensitivity of sensory fibers and reflex pathways in patients with I-OAB. Botulinum toxin has been shown to block both the afferent and efferent fibers, resulting in a decreased sensation of fullness, and reduced smooth muscle contractility, respectively [32–34]. Different strains of botulinum toxin (A to F) interact uniquely with different SNARE proteins, which are required for the release of acetylcholine from the presynaptic terminals. These interactions inhibit cholinergic neurotransmission at neuromuscular synapses and subsequently decrease or abolish muscle contractions [35]. BTX-A has the longest duration of action and has become the focus of medical applications.

There are five different preparations of BTX-A: onabotulinumtoxinA (Botox™), abobotulinumtoxinA (Dysport™), incobotulinumtoxinA (Xeomin™), Prosigne™, and Purtox™. Studies suggest that 1 unit of onabotulinumtoxinA is roughly equivalent to 3–5 units of abobotulinumtoxinA, 1 unit of Xeomin, and 1 unit of Prosigne, although no randomized control trials comparing dose, efficacy, and safety exist [36]. OnabotulinumtoxinA and abobotulinumtoxinA are the most commonly used preparations. Studies on abobotulinumtoxinA show similar treatment efficacy to onabotulinumtoxinA [36–39]. AbobotulinumtoxinA has been studied at doses of 500, 750, or 1000 U; 500 U resulted in too short a duration of action, while side-effects with 1000 U were too great (reports of temporary generalized weakness) [40]. A study by Jeffery et al. demonstrated a clean intermittent catheterization (CIC) rate at six weeks of 35% for treatment of I-OAB with Dysport 500 U [39]. Revindra et al. also showed abobotulinumtoxinA 500 U had a rate and duration of efficacy similar to that of onabotulinumtoxinA 200 U, but they demonstrated a higher rate of CIC in the abobotulinumtoxinA group (42% vs. 23%) [38]. The majority of evidence on BTX-A therapy in OAB is with onabotulinumtoxinA use. Because of this, the remainder of the discussion will focus solely on onabotulinumtoxinA.

## Results of onabotulinumtoxinA injection

The efficacy of injection of onabotulinumtoxinA into the detrusor smooth muscle of the bladder wall of patients with refractory N-OAB was first demonstrated by Schurch et al. in 2000 [41]. In this study, 21 patients with spinal cord injury who experienced incontinence secondary to neurogenic detrusor overactivity, required CIC to empty, and had failed anticholinergics were treated with onabotulinumtoxinA. Following treatment they demonstrated a significant increase in mean maximum bladder capacity (from 296 to 480 ml, $P < 0.016$) and a significant decrease in mean maximum detrusor voiding pressure (from 65 to 35 $\mathrm{cmH_2O}$, $P < 0.016$). Of the 21 patients, 17 were completely continent at six weeks follow-up and were satisfied with the procedure; improvements in urodynamic parameters and incontinence persisted at 36 weeks in 11 patients [41]. Since that initial description, many studies have demonstrated the utility of onabotulinumtoxinA injection as an appropriate therapy for patients with I-OAB and N-OAB refractory to anticholinergics [3, 4, 36–71].

## Neurogenic overactive bladder

Multiple placebo-controlled studies have demonstrated the efficacy of onabotulinumtoxinA in patients with N-OAB [45–51]. Two recent double-blind, placebo-controlled, Phase 3 studies demonstrating the efficacy of onabotulinumtoxinA in patients with N-OAB provide the strongest evidence for its use [48, 49]. A total of 691 patients with N-OAB secondary to multiple sclerosis (MS) or spinal cord injury (SCI) were included in a pooled analysis [48–50]. Patients were included if they had >14 episodes of urge incontinence per week and had failed a trial of appropriately dosed anticholinergic medication for >one month due to inefficacy or intolerance. Patients were then randomized to receive intradetrusor injections of 30 ml of onabotulinumtoxinA 200 U, 300 U, or placebo. The trigone was spared during injection. Six weeks following treatment statistically significant decreases in weekly urge incontinence episodes were seen in the 200 U (−22.6 MS, −19.6 SCI) and 300 U (−24.0 MS, −18.2 SCI) group compared to placebo (−14.0 MS, −6.4 SCI). In addition, rates of total continence at six weeks increased in both the 200 U (41.5% MS, 30.9% SCI) and 300 U groups (44.2% MS, 35.9% SCI) compared to placebo (10.7% MS, 7.3% SCI). Significant increases in I-QOL scores were seen in both onabotulinumtoxinA groups compared to placebo. Urodynamic studies (UDS) performed at six weeks after injection demonstrated an increase in maximum cystometric capacity (MCC) compared to placebo (151–157 ml, 157.2–168 ml, and 6.5–18 ml). Mangera et al. performed a systematic review of available literature in 2014 supporting these findings. They reported statistically significant improvements in daily incontinence (−63%) as well as multiple UDS parameters, including MCC (+68%) [37].

The FDA-approved starting dose for onabotulinumtoxinA in the treatment of N-OAB is 200 U. Apostolidis et al. showed 200 U to be the most effective dose in a placebo-controlled dose-response study comparing 50, 100, and 200 U onabotulinumtoxinA [51]. In the previously discussed Phase 3 studies the 300 U dose did not add to the clinical efficacy in any subpopulation compared to 200 U [48–50].

## Idiopathic overactive bladder

The American Urological Association (AUA) and Society of Urodynamics, Female Pelvic Medicine and Urogenital Reconstruction (SUFU) released an amendment to the 2012 non-neurogenic OAB guideline statement upgrading the use of onabotulinumtoxinA (100 U) as third-line treatment from an option to standard [3, 4]. This was largely based on updated review of the literature with 27 new studies including five randomized trials with placebo control groups and 2 trials with active controls [4]. Several randomized, double-blind trials were performed demonstrating the efficacy and tolerability of 100 U onabotulinumtoxinA [52–61]. The largest Phase 2 trial was performed by Dmochowski et al. who compared 50 U, 100 U, 150 U, 200 U, and 300 U onabotulinumtoxinA to placebo [52]. They found 100 U to be the optimal dose to improve UI episodes and other OAB symptoms, while doses of 150 U or greater led to a dose-dependent increase in postvoid residual (PVR) without providing additional clinical benefit. Two Phase 3 double-blind, placebo-controlled trials performed by Chapple et al. and Nitti et al. provide the most robust evidence, showing a three- to fourfold decrease in frequency of UI episodes in 100 U onabotulinumtoxinA compared to placebo [62–64]. Pooled analysis of the data included 1097 patients with at least three UI episodes per three days and eight micturitions per day who had failed anticholinergic therapy due to inefficacy or intolerance. Subjects were then randomized to onabotulinumtoxinA 100 U or placebo divided in 20 detrusor injections. The trigone was spared during injection. The onabotulinumtoxinA group demonstrated a significant improvement in UI episodes per day compared to placebo (−2.8 vs. −0.95) at 12 weeks. The onabotulinumtoxinA arm also demonstrated 27.1% rate of total continence compared to 8.4% in the placebo arm. Furthermore, patients who received onabotulinumtoxinA were more likely to report improved frequency and urgency. A systematic review of available literature in 2014 reported statistically significant decrease in daily incontinence (−59%) as well as improvement in multiple UDS parameters including MCC (+58%) [37].

Rovner et al. demonstrated objective improvement in MCC on UDS in patients treated with onabotulinumtoxinA 100 U at 12 weeks compared to placebo (+71.0 ml vs. +49.5 ml), as well as improved compliance at MCC (+63.0 vs. 22.8 ml/cm$H_2O$) [65]. Of note, the presence of detrusor overactivity on baseline UDS did not impact the efficacy of onabotulinumtoxinA injection for patients with I-OAB. Because of this, routine UDS testing is not required prior to treatment with onabotulinumtoxinA for I-OAB [66].

## Pediatric overactive bladder

Pediatric patients with myelomeningocele experience difficulty with bladder function, and many suffer from detrusor overactivity and incontinence. In addition, there is concern for deterioration of their upper tracts as they may have high bladder pressures due to poor or intermediate compliance and vesicoureteral reflux. OnabotulinumtoxinA is not currently approved for use in pediatric OAB, however multiple studies have demonstrated clinical benefit. Mangera et al. performed a systematic review of available literature on onabotulinumtoxinA use in pediatric N-OAB refractory to medical management. OnabotulinumtoxinA treatment was found to improve MCC from 50% to 59% and maximum detrusor pressure decreased from 42% to 50% [37]. In addition, a reduction in the grade of vesicoureteral reflux was noted in one study, potentially as a result of decreasing bladder pressure [66]. Use of onabotulinumtoxinA in pediatric patients is being investigated for treatment of OAB in non-neurogenic patients with positive preliminary data [67, 68]. Urethral external sphincteric injection of onabotulinumtoxinA in children with dysfunctional voiding has been shown to be beneficial as well [69–71].

## Repeat injections

As the effects of onabotulinumtoxinA injection have been shown to last approximately 6–9 months, patients require repeat injections to continue to experience the therapeutic benefits. Initially there were concerns raised regarding the possibility that repeat injections would result in a blunted response over time due to antibody formation to the toxin. Several studies in N-OAB patients have evaluated the efficacy of repeat injections of onabotulinumtoxinA with five to seven injections over a 6- to 8-year period, and have demonstrated that urodynamic and clinical improvements in QOL and decreased medication requirements after the first injection were maintained for a duration of 6–9 months after each subsequent application [72–76]. In addition, it was postulated that repeat injections could result in fibrosis from repeated puncturing of the mucosa; however, several studies have investigated this and found no evidence of it [77–79].

## Adverse outcomes

Adverse outcomes associated with the injection of onabotulinumtoxinA include mild hematuria, dysuria, systemic toxicity, UTIs, and urinary retention requiring CIC. OnabotulinumtoxinA carries a black box warning from the FDA due to risk of toxin spread from the site of injection, which may cause difficulty swallowing or breathing and in very rare instances risk of death. The risk of symptoms is probably greatest in children treated for spasticity but may occur in adults. Additional signs of systemic toxicity include hypoasthenia, impaired vision, extremity weakness, dry mouth, dysphagia, and constipation [65]. Systemic onabotulinumtoxinA toxicity is uncommon after intradetrusor injection and more often associated with higher doses administered for nonurologic reasons by other specialties [80]. Peripheral muscle weakness has also been noted to occur in rare instances, and has been associated with patients receiving a higher dose (1000 U) of abobotulinumtoxinA [40, 72]. When treating adults for one or more indications, the total cumulative dose of abobotulinumtoxinA is not to exceed 400 U over a three-month interval.

Rates of UTI following onabotulinumtoxinA injection range from 3.6% to 54% in the literature [3]. This variability may depend on patient-related factors as well as the indication for onabotulinumtoxinA therapy. In the two Phase 3 trials of onabotulinumtoxinA in N-OAB, patients with SCI had a UTI rate of 44.8%, similar to a rate of 49.5% of patients with SCI who underwent placebo. Patients with MS who underwent onabotulinumtoxinA therapy for N-OAB had a higher rate of UTI compared to placebo (53.5% vs. 29.2%), which is likely explained by higher rates of urinary retention requiring *de novo* CIC in this patient population. A systematic review of onabotulinumtoxinA use in I-OAB found a UTI rate of 21% compared to 7% in the placebo group and a rate of 39% for patients with N-OAB compared to 33% following placebo injections [37].

In general, an increase in PVR can be expected following onabotulinumtoxinA injection; however, the definition of urinary retention and the threshold for initiation of CIC differs among the various studies. Dmochowski et al., who compared 50 U, 100 U, 150 U, 200 U, and 300 U onabotulinumtoxinA to placebo found a dose-related increase in PVR [52]. Phase 3 trial data on onabotulinumtoxinA use for I-OAB reported CIC rates of 6.5% after onabotulinumtoxinA 100 U versus 0.4% in the placebo group [60–64], while a literature review reported a 12% rate of CIC in this population [37]. Phase 3 trial data on onabotulinumtoxinA use for N-OAB with MS reported a posttreatment CIC rate of 40% with onabotulinumtoxinA 200 U and 51% with 300 U, compared to 17% with placebo [48–50]. The need to perform CIC may not be an issue for a patient with N-OAB who has likely had to perform CIC in the past, while the need for *de novo* CIC may prove very bothersome in a patient who has never had to do so. However, the need for postprocedure CIC did not impact patient satisfaction in the N-OAB population [48–50]. While many of our N-OAB patients are already proficient in performing CIC, we prefer to teach all our patients CIC, including the I-OAB patients, prior to treatment.

CIC usually needs to be performed for about 1–3 months until PVR decreases as the effects of the onabotulinumtoxinA wear off. Of note, rates of CIC are significantly increased following repeat injections in patients who experienced retention with a prior injection [81, 82]. Factors that can predict a need for *de novo* CIC are a projected isovolumetric detrusor pressure of less than 50 in women (sensitivity 0.83, specificity 0.7) and a bladder contractility index of less than 120 in men (sensitivity 0.7, specificity 0.79) [82].

## Technical considerations

OnabotulinumtoxinA injection into the bladder wall can be accomplished using either rigid or flexible cystoscopy using local, regional, or general anesthesia [65], although general anesthesia is rarely needed. The technique was originally described by Schurch et al. using a rigid cystoscope and an endoscopic needle to inject 1 mL just beneath the detrusor epithelium at 20–30 sites, sparing the trigone (see Video 154.1) [41]. Later the "Dasgupta technique" was described using a flexible cystoscope: a sheath is passed through the working channel of the cystoscope to protect the scope during passage of a 27G needle and to stabilize the needle during injection [83]. In addition, a minimally invasive sedation-free technique can be performed by instilling 40 ml of 1% lidocaine into the bladder via a catheter 10 minutes prior to cystoscopy [84, 85]. Thus, onabotulinumtoxinA injection can be performed in the operating room or office with either a rigid or flexible cystoscope, depending on surgeon preference. The FDA has approved 100 U of onabotulinumtoxinA for treatment of I-OAB and 200 U of onabotulinumtoxinA for treatment of N-OAB. The onabotulinumtoxinA is diluted in 20 ml of sterile saline for 100 U and 30 ml for 200 U. It is then injected in 0.5–1 ml increments through the detrusor, separated by a distance of 1–1.5 cm. The standard depth of onabotulinumtoxinA injection is to the detrusor layer of the bladder wall, although some research suggests a benefit of suburothelial injections. OnabotulinumtoxinA delivered to the suburothelial space may modulate the release of sensory nerve endings and potentially inhibit detrusor overactivity mediated by sensory nerve dysfunction [86–88]. Studies have shown similar benefits between suburothelial and intradetrusor injections, although suburothelial injections may be associated with higher rates of voiding dysfunction [86–88].

Some controversy exists regarding whether the trigone is included or spared from injection. Many of the initial studies advocated avoiding injection of the trigone as urologists felt it could lead to vesicoureteral reflux; however, this has not been shown to occur in two prospective studies [89, 90]. One study showed a greater effect on reducing urgency sensation in I-OAB [91]. Kuo et al. compared outcomes for 100 U onabotulinumtoxinA injections in the bladder body, bladder body plus trigone, and bladder base plus trigone and found no difference in success rate (70–74%), changes in urgency, or adverse events [92], and a meta-analysis comparing trigonal and extratrigonal injection sites also found no differences in short-term efficacy or adverse events [93]. Studies have also explored injection of the external (striated) sphincter in patients at risk for urinary retention with some positive preliminary results, however the utility of urethral sphincteric onabotulinumtoxinA injection for non-neurogenic voiding dysfunction is unclear [94–96].

## Conclusions

A moderate percentage of patients with OAB, either from idiopathic or neurogenic causes, are refractory to behavioral modification and oral medications. Endoscopic injection of BTX-A into the detrusor wall is well-established as an alternative therapy in these patients as multiple randomized, double-blind trials have demonstrated clinical and urodynamic efficacy, resulting in fewer incontinence episodes, improved QOL, and increases in bladder capacity and decreases in maximum detrusor pressures. These beneficial results last approximately 6–9 months and injections can be repeated as necessary with no apparent tachyphylaxis. In general, this treatment is well tolerated. However, patients can experience increased residual volumes requiring CIC for 1–3 months until spontaneous voiding can resume, and also are at a higher risk for UTIs.

# STING Procedure for Reflux

*Steve J. Hodges*

*Institute for Regenerative Medicine, Wake Forest University School of Medicine, Winston-Salem, NC, USA*

## Introduction

The endoscopic treatment of vesicoureteral reflux (VUR) involves the injection of a bulking agent at the orifice of an incompetent ureter in order to create a suitable flap–valve mechanism to prevent the retrograde flow of urine during voiding. Many different types of bulking agents have been used in the history of endoscopic reflux therapy, although the perfect agent has been elusive. The ideal substance for endoscopic treatment of reflux should be easily injectable, nonimmunogenic, stable, and safe for human use [1].

## Search for the ideal bulking agent

Matouschek was the first to describe the endoscopic treatment of VUR in 1981 when he described the injection of Teflon® polytetrafluoroethylene (PTFE) at the ureteral orifice to increase resistance to urine back flow [2]. Following the publication of excellent results using the subureteral PTFE (Teflon) injection (the STING technique) by O'Donnell and Pruri, the procedure received general acceptance in Europe, but was not widely used in the United States, where there was concern over implant migration [3]. The numerous reports of PTFE migration to remote areas such as the brain and lung following injection in the urethra and bladder neck sealed the fate of PTFE therapy [4, 5]. In addition to the risk of migration, there was concern over the development of granulomatous reaction around the PTFE, leading to possible calcification and making subsequent reimplant surgery difficult [6].

Once it was clear the future of the endoscopic treatment of reflux would not include PTFE, scientists searched for other agents to be used in the desirable technique. Silicone (Macroplastique; Urpoplasty Inc., Minneapolis, MN, USA) was a very effective agent when used with the STING procedure, correcting reflux in over 80% of ureters, with little morbidity. Unfortunately, silicone can cause a local foreign body reaction, and on the basis of the variable size of its particulates (35–540 μm), has a theoretical potential for migration risk. Also, the difficulty in injecting the viscous solution made the procedure less desirable. Finally, Macroplastique came to light at a time of great concern over systemic collagen disorders arising from silicone implants, and the material never achieved popular use [1, 7]. Recently, however, studies have demonstrated improved results with polydimethylsiloxane as compared to commonly used agents (specifically with high-grade reflux), raising the question as to whether this material should be revisited as a viable alternative [8].

The next agent to be explored for the endoscopic therapy of reflux was glutaraldehyde crosslinked bovine collagen (Contigen; C.R. Bard Inc., Murray Hill, NJ, USA). This substance has several characteristics that limited its widespread use for the STING procedure. First, it has the possibility of an allergic reaction, and therefore demands requisite allergy testing preinjection. Also, as has been noted in other areas of collagen injection (in cosmetic surgery, or the urethra for intrinsic sphincter incontinence), the substance has a limited staying power, and can show significant volume loss over time from the site of injection. Finally, long-term efficacy was not comparable to other, more durable agents [1, 7].

Calcium hydroxylapatite (Coaptite; Boston Scientific Inc., Natick, MA, USA) is a mixture of water and glycerin with 3% methylcellulose gel. It had commendable results in studies on patients with reflux requiring endoscopic correction, but had a higher single injection failure rate when compared to competing agents.

The material is thought to be biocompatible and nonmutagenic, and currently is indicated only for female stress urinary incontinence secondary to intrinsic sphincter deficiency [1].

As research into tissue engineering expanded in the 1990s, one of the first areas investigated for human use involved the growth of chondrocytes for the treatment of VUR in children. Autologous chondrocytes were harvested from the auricular cartilage of patients and six weeks after their harvest and growth in culture, they were suspended in an alginate solution that included calcium chloride and calcium sulfate, which provided a scaffold for cartilage formation. The cells were then injected cystoscopically using the STING technique. The elastic cartilage tissue formed was able to correct VUR without any evidence of obstruction, and represented the first human application of cell-based tissue engineering technology for urologic applications [9].

However, the costs of the technique, as well as the need for a second harvesting procedure, limited the widespread use of the technology. In addition, variable degrees of cell growth appeared to occur, leading to inconsistent success rates [10].

Another novel material for use in the STING procedure was introduced in the late 1990s. Crosslinked dextranomer and hyaluronic acid (Deflux) had been used safely in the body for other indications for years, with no migration and long-term durability. Deflux was thought to have many of the characteristics of an ideal and effective bulking agent, as it is thin enough to allow needle injection, yet viscous enough to maintain its volume, is biocompatible, elicits minimal inflammation, and maintains its periureteral configuration over time [11].

In the first few years after the introduction of Deflux and its acceptance into widespread use, it demonstrated excellent results and durability, and had become the agent of choice. As the experience with the use of Deflux grew, the techniques, methods, and circumstances of use evolved.

As the years have passed, complications have arisen from the use of Deflux as well, with overall success rates only in the 70% range, and reports of the implant causing long-lasting inflammation and the formation of granulomas, and pseudocysts around the Deflux injection site. In many cases the implant has become calcified, mimicking a ureteral calcification on imaging studies, and the incidence of early and obstruction as a result of Deflux injection is increasing [12, 13].

In instances where Deflux is being considered as a treatment option, another dextranomer/hyaluronic acid-based bulking agent (Vurdex; BioScience GmbH, Germany) has been developed, with similar results to Deflux but a significantly lower price [14].

## Technique

The traditional STING procedure involved the injection of bulking material just outside the ureteral orifice at the 6 o'clock position, elevating a mound with the compressed ureteral orifice located at the top of the hillock. Using the traditional STING technique, the success rates with Deflux injection, while variable, were acceptable, but certainly lagged behind those of surgical reimplantation. The Atlanta group pioneered a novel method, termed "HIT" and now "double HIT," which has raised the success levels of Deflux injection above 90% [15, 16]. In this method, the ureter is hydrodistended so that the needle may be placed inside the ureteral tunnel, a few millimeters within the orifice (see Video 155.1). This allows the first injection of the HIT technique to track bulking agent along the ureteral sheath, and more efficiently coapt the ureter (especially larger, dilated ureters). The second hit is similar to the traditional STING injection, but is slightly more cephalad, and coapts the ureteral orifice and elevates a mound of bulking material at the terminal ureter (see Video 155.2 for the complete double HIT technique). This technique creates a "mountain range" of bulking material along the course of the ureter, in contrast to the original simple hillock (Figures 155.1 and 155.2) [17].

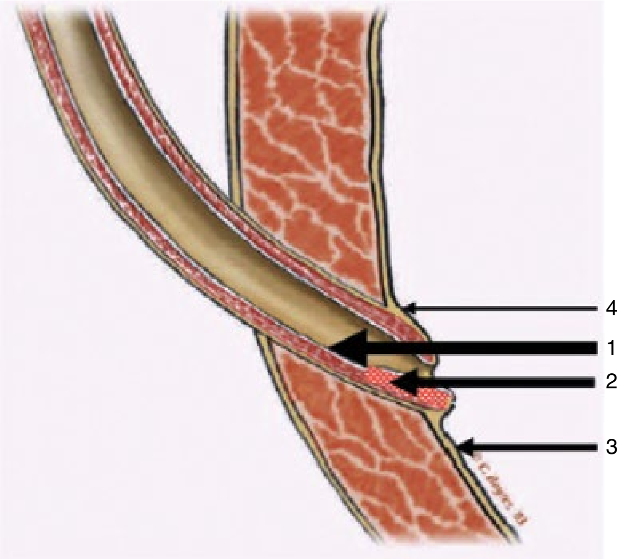

**Figure 155.1** Locations of needle placement for the **1**, intraureteric proximal technique (HIT); **2**, intraureteric distal technique (double HIT); **3**, traditional STING technique; and **4**, superior tunnel. *Source:* Kuipers S, van der Horst EH, Verbeke JI, et al. Prevesical calcification and hydronephrosis in a girl treated for vesicoureteral re-flux. *Glob Pediatr Health* 2016;3:2333794X16652272. Reproduced with permission of Elsevier.

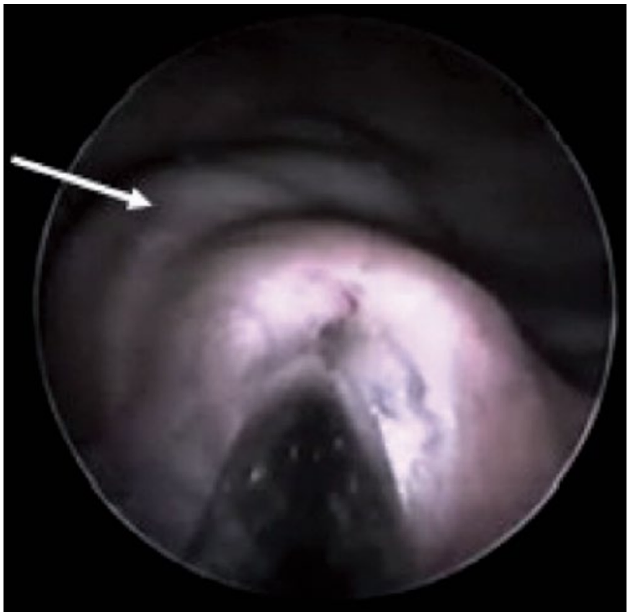

**Figure 155.2** "Mountain range" mound (arrow) produced by the double HIT injection technique. *Source:* Kuipers S, van der Horst EH, Verbeke JI, et al. Prevesical calcification and hydronephrosis in a girl treated for vesicoureteral re-flux. *Glob Pediatr Health* 2016;3:2333794X16652272. Reproduced with permission of Elsevier.

The double HIT method has not only been employed for primary VUR (90% cure), but also for repeat endoscopic injections (90%), VUR associated with paraureteral diverticula (81%), complex cases such as post reimplantation (88%), neurogenic bladders (78%), duplication anomalies (80%), and in adults (88%). Several other studies have supported the use of Deflux in the setting of anatomic variants such as duplex systems as well [17–20].

The experience with the double HIT technique was also important in identifying the need for sometimes large volumes of injectable material for cure. There is considered to be a 20% volume loss over time when using Deflux, so as a matter of technique it is important to use an adequate amount of material so that cure is ensured. Limiting the amount injected in an effort to limit costs often results in increased expenses later as failure rates are higher [21]. Also, failure is usually due to caudal migration of the bleb, so more proximal injection using the double HIT method, as well as the larger volumes, has improved results [17].

The use of hydrodistention in these procedures also led to studies correlating the degree of ureteral distention with reflux. A grading system has been developed for ureteral dilation, which correlates well with grade of reflux. The hydrodistention grading system defines grades of reflux as: H0, no hydrodistention; H1, ureteral orifice open but tunnel not evident; H2, tunnel seen only, and H3, extravesical ureter visualized (Figure 155.3). In studies, VUR and dynamic hydrodistention classification grades correlate significantly ($P < 0.001$), and provide a reliable method of evaluating the presence or absence of VUR. These findings, combined with the studies demonstrating a lack of correlation of intraoperative cystogram and late cure, have allowed surgeons to do away with the postoperative cystogram (at the time of the injection), as lack of hydrodistention can confirm cure [15, 22].

## Follow-up

Follow-up for STING procedures varies. As mentioned, it has been determined that a cystogram is not needed at the time of injection, as ureters that do not hydrodistend are considered cured. Cystography may, however, pick up contralateral unrecognized reflux, which may then be easily treated [23].

Traditionally, patients are observed for approximately three months on prophylactic antibiotics and then studied with renal bladder ultrasound and voiding cystourethrogram (VCUG) following injection therapy. In cases where the expected cure rate is high, the VCUG may be avoided and children do well. There has been some research into the appearance of injected bleb on postoperative ultrasound and cure rate. One study has demonstrated that while there is no difference in the volume of the visible Deflux on postoperative ultrasound in cures and failures, when a greater than expected volume of Deflux is retained (termed mega-implant), the cure rate is much higher than in cases with a less than expected volume remaining (micro-implants) or no visible implant [21]. The same study demonstrated durable implant size over 36 months postoperatively in these patients [21].

The bleb at the site of Deflux injection can persist long term, and this raises issues for future imaging and misinterpretations of the mass. Studies have demonstrated that the blebs can appear as calcifications on computed tomography (CT) scans and be mistaken for ureteral stones, and appear bright on T2-weighted images, but do not enhance on T1 scans [24–26]. It is important to note the history of intervention in these patients, so unnecessary medical interventions are not performed for these findings. The pathologic description of Deflux material has also been well described, so any tissue sent for pathologic evaluation in cases of reimplantation after injection therapy should be readily identifiable [27].

Long-term data regarding Deflux are now available, with some studies demonstrating durable results, while others show declining success rates over the long term, and yet others demonstrating the risk of possible late obstruction. However, it is important to keep in mind that in most cases the patients with late failures had risk factors, such as dysfunctional elimination, which may

| Hydrodistention grade | Description | Cystoscopic appearance | Example |

have contributed to the poor results. It seems prudent to follow these children closely for several years to rule out treatment failures or other complications such as obstruction [28–30].

## Role of the STING procedure

Typical of many areas in pediatric urology, the treatment of VUR is highly controversial. The opinions on STING therapy for reflux vary from religious opposition to overzealous support. The exact role for endoscopic reflux therapy remains to be defined, but it is clear that it is gaining a more prominent position in the armamentarium of the surgeon treating various forms of reflux. Studies have expanded its role from simple refluxing ureters to more complex systems, such as duplicated ureters, ureters associated with diverticula, transplant ureters, and even ureters in neurogenic bladders. The appeal of STING therapy to many is that the procedure poses minimal morbidity with the chance of great reward if a cure results. If cure is not achieved, the grade of reflux is often downgraded to a less clinically significant level, and repeat injections may also be performed. Once STING has failed twice, all experts agree that any surgical intervention needed should then proceed to open reimplantation, and surgery following even repeat injection procedures is only slightly more difficult than virgin surgery. In summary, this procedure may offer a simple cure, while not burning any bridges [31].

There is a concern that Deflux injection, being a relatively simple procedure, will be overutilized to the detriment of patients. As with any technology or procedure, the clinician's judgment is crucial to the success of the methodology chosen, and judicious use of any technique is a must [32]. Some have attempted to push the envelope with mixed results. Deflux has been used in combination with botulinum toxin A injection as a means of total endoscopic management of a noncompliant neurogenic bladder. These combined therapies were able to decrease bladder pressure and the rate of urinary tract infections (UTIs), but is not a likely long-term viable solution to a high pressure neurogenic bladder with secondary reflux [33].

The detractors of STING therapy point to studies expressing low cure rates per ureter, extolling that it is in the best interests of the patient to provide a one-time, highly successful surgery. The proponents rely on the support of studies stating higher cure rates, and the "less is more" philosophy of surgical intervention. It seems that these differences are often philosophical, and depend on the personality, experiences, and training of the surgeon, and all the studies published have done little to sway adherents from either camp to the other side.

A unique benefit of the STING procedure is that it can easily be paired with a positionally instilled cystogram (PIC) as a simple procedure to diagnose and treat VUR. Studies have demonstrated that children with recurrent febrile UTIs with negative VCUG studies may have occult reflux (as VCUGs have a known false-negative rate), and these cases can be diagnosed and treated with PICs followed by Deflux injections. The PIC is performed by using cystoscopy with contrast running as the irrigation fluid and pointing the beak of the cystoscope at the ureteral orifice in a partially filled bladder. Fluoroscopic images of reflux are considered proof positive of occult reflux, and treatment with STING therapy is almost always the next option. Considering the relation of ureteral hydrodistention and reflux grade, it may be debatable as to whether contrast instillation is necessary in an obviously distended system (grade 3), but documentation of the pathology is always helpful in justifying the therapy [34, 35].

Another interesting area of research into the uses of the STING procedure for reflux therapy has been the push by proponents of the technique to use it as a first-line therapy for reflux. These authors point to the low patient compliance with prophylactic antibiotics, claiming that first-line injection therapy would be a more inexpensive, simpler option for families, with little morbidity. For example, Hensle et al. noted that only 17% of patients with VUR on prophylaxis are compliant and that 58% had a diagnosis of UTI within 1 year of treatment [36]. Elder et al. demonstrated that treatment with Deflux in children with reflux resulted in fewer UTIs than management with prophylactic antibiotics, and concluded that Deflux should be considered first-line therapy [37]. Koyle and Caldamone made a case that misuse of antibiotics has spread resistance, and thus should be replaced by first-line Deflux therapy in appropriate patients [38].

There has historically been a general lack of controlled studies regarding prophylaxis for vesicoureteral reflux, although the RIVUR study (Randomized Intervention in Children with Vesicoureteral Reflux) demonstrated that antimicrobial prophylaxis was associated with a reduced risk of recurrent UTIs [39]. In general, compliance is low with antibiotic prophylaxis, but that does not mean that the therapy is ineffective or not worthwhile. When given appropriately, prophylaxis does prevent infections, and does not have a large impact on microbial resistance [40]. All parents should have all options discussed with them on visits with their child's pediatric urologists (from open surgery to prophylaxis), and prophylaxis remains standard first-line therapy. New innovations, including injection therapy, should be closely studied and offered in an unbiased fashion.

With the availability of minimally invasive techniques, such as extravesical ureteral reimplantation, mini-ureteroneocystostomy, and extravesical and intravesical laparoscopic and robot-assisted procedures, there has been a push by some surgeons to prove that traditional ureteral reimplantation can be performed with new techniques and technology in an outpatient setting, with comparable morbidity and higher cure rates than with endoscopic procedures. Some studies have also demonstrated decreased total cost with these procedures. It is clear that as minimally invasive surgical technology advances, there will be pressure on the endoscopic options of therapy to maintain high cure rates to compete with these increasingly inexpensive and benign procedures [41–43].

The choice of therapy for VUR remains controversial. The main goal of preventing renal scars and infection in these young children must be kept in mind, and we are fortunate to have a multitude of excellent options to choose from to achieve this goal. In the hands of a trained pediatric urologist, with close follow-up of their patients, all three options of antibiotic prophylaxis, STING therapy, and open surgery can be used wisely in an effort to maintain urologic health.

## Dysfunctional elimination

It is our opinion that as the identification and treatment of dysfunctional elimination improves, the rates of resolution of refluxing ureters will also improve (as well as the success rates of STING procedures), obviating the need for open surgery in most children [40]. In fact, the Atlanta group currently reserves open surgery only for patients who fail injection therapy (two injections), have high-grade reflux or megaureters (that require tapering), and if this is the preference of the parents [17].

Results have been published showing that the treatment of dysfunctional elimination does not affect the success of endoscopic therapy of reflux, but the definition of dysfunctional voiding and the documentation of its successful treatment are not always well documented or proven [17, 44, 45]. Our center has unpublished data showing that the incidence and severity of dysfunctional elimination is widely underestimated, and that a focus on biofeedback and constipation therapy may greatly reduce the incidence and severity of reflux in children.

## Conclusions

The introduction of Deflux into the realm of endoscopic reflux therapy has provided surgeons with an almost ideal bulking agent, and allowed for the expansion of the STING procedure. The techniques have improved, as well as the results, and endoscopic therapy has become a reasonable option for almost all children with reflux, and in some circumstances a good first option. As the treatment of dysfunctional elimination becomes more codified and widespread, the need for open surgery will likely wane, while the numbers of endoscopic cases will continue to expand. The growing experience among practicing urologists, standardization of techniques, and introduction of new tools that help the consistency and accuracy of needle placement (Figure 155.4) will help ensure reproducibly high success rates for endoscopic therapy in the future.

# Minimally Invasive Therapy for Bladder Pain Syndrome (Interstitial Cystitis)

*Ricardo Palmerola*[1], *Sandeep Gurram*,[2] *& Robert Moldwin*[2]

[1] *New York University Langone Medical Center, New York, NY, USA*
[2] *The Arthur Smith Institute for Urology, Zucker School of Medicine at Hofstra/Northwell, New Hyde Park, NY, USA*

## Introduction

Interstitial cystitis/bladder pain syndrome (IC/BPS) is a chronic pain syndrome affecting both men and women and characterized by irritative voiding symptoms (urinary frequency, urgency, dysuria, nocturia), and pelvic organ pain exacerbated by bladder filling [1]. The clinical diagnosis of BPS is challenging, as patients may present with a myriad of symptoms resembling other urologic, gynecologic, or gastrointestinal conditions. As such, BPS is a diagnosis of exclusion that requires a multimodal treatment approach. This chapter will review IC/BPS with a focus on minimally invasive treatment options.

## Definition/nomenclature

IC/BPS is a clinical syndrome where patients report "an unpleasant sensation" (pain, pressure, discomfort) perceived to be related to the urinary bladder, associated with lower urinary tract symptoms of more than six weeks duration, in the absence of infection or other identifiable causes [2]. Once considered a disease related only to the bladder, it is becoming increasingly evident that this syndrome is associated with other pain syndromes and medical conditions affecting multiple organ systems [3].

Patients can be categorized into two separate subtypes of IC/BPS, and management can vary depending upon the clinical findings. "Classical" IC/BPS is characterized by the presence of erythematous patches in the bladder mucosa known as Hunner's lesions, which were described nearly 100 years ago by Guy Hunner [4] (Figure 156.1). In addition to erythematous mucosa, Hunner's lesions contain a central scar and can be associated with glomerulations that may bleed as the bladder empties [5]. Only cystoscopy can accurately determine if inflammatory disease is present, and only 30% of IC/BPS patients demonstrate abnormalities on urinalysis that would prompt cystoscopic evaluation [6]. Thus the true incidence of Hunner's lesions in IC/BPS patients is unknown and incidence ranges between 5% and 50% [7]. Alternatively, patients with "nonclassical" disease are characterized by a normal cystoscopic examination in the face of typical symptoms and normal cystoscopic findings.

## Epidemiology

Considering the difficulty of establishing an accepted definition, collected data have been difficult to interpret, leading to variations in the reported prevalence internationally. In a large study from Finland, the estimated prevalence in women was 230 per 100 000, and a study of urban females in Vienna, Austria gave an overall estimate of 306 per 100 000 women, with the highest prevalence (464 per 100 000) among middle-aged females (40–59 years old) [8, 9]. Similarly, a population-based study in the United States found the prevalence to be 197 per 100 000 women and 41 per 100 000 men [10]. In a recent population-based prevalence study, the Rand Corporation contacted a random sample of 146 231 homes via telephone. Using a case definition with high specificity for IC/BPS, nearly 3% met criteria for IC/BPS. According to the study, approximately 3.3 million women in the United States met criteria for IC/BPS [11]. Screening and data collection based on symptoms rather than diagnosis show the prevalence to be much higher. A primary care office survey screening patients for symptoms of IC/BPS estimated the prevalence to be 12 600 per 100 000 women [12]. Studies by Parsons et al. suggest that IC is highly prevalent in young women

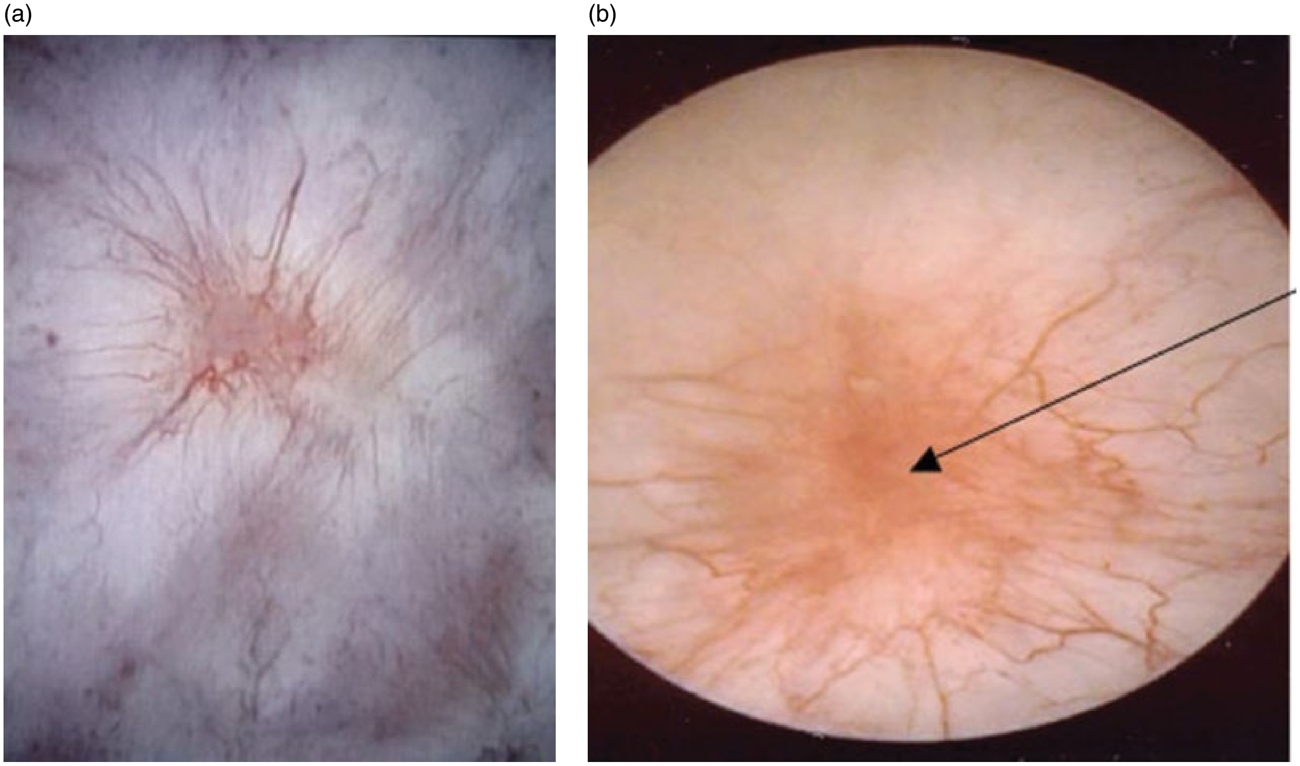

**Figure 156.1** Hunner's lesions: erythematous patches typically found in extratrigonal position in interstitial cystitis/bladder pain syndrome (IC/BPS) patients (a), the arrow indicates the central scar often seen in these lesions (b).

and may affect as many as one in four [13, 14]. The estimated female-to-male ratio is estimated to be 5:1 or higher [9, 15]. Furthermore, men tend to present at an older age and based on prior reports have a higher incidence of Hunner's lesions [16, 17].

Most patients diagnosed with IC/BPS are adults, but the condition has been reported in children and young adults [18, 19]. A history of pediatric voiding dysfunction, such as dysfunctional voiding or enuresis, is reported to be 10 times higher in IC/BPS patients versus the general population.

IC/BPS is a chronic condition and unfortunately has a profoundly negative impact on patient's quality of life [15]. In addition to affecting overall mental health and sexual function, IC/BPS often coexists with depression, chronic pain syndromes (fibromyalgia, temporomandibular disorder, and chronic fatigue syndromes), and irritable bowel syndrome [15, 20–22].

## Etiology

Numerous explanations and etiologies for IC/BPS have been proposed, suggesting that the disease is the manifestation of multifactorial causes working through numerous pathways. Existing data also supports the theory that IC/BPS may be a systemic disorder, with bladder symptoms and pelvic pain being the primary manifestation [23, 24]. Evidence exists for a genetic component to IC/BPS. Adult female first-degree relatives of patients with IC/BPS are reported to have a prevalence 17 times that found in the general population [25]. In a study including >25 000 twins born between 1959 and 1985, less than one-third of female twins had genetic factors playing into susceptibility of BPS [26]. In addition, there is a greater concordance of IC/BPS among monozygotic than dizygotic twin pairs, strengthening the evidence for genetic susceptibility to IC/BPS [27].

An infectious etiology for IC/BPS has been proposed to explain the initial insult in the pathogenesis of IC/BPS. Various pathogens, including bacteria, viruses, and fungal organisms, have been investigated. However, highly sensitive and specific molecular methods for identifying infectious agents by detection of DNA or RNA were unable to demonstrate any particular microorganism responsible for the development of IC/BPS. Another infection-related theory is that pathogens subvert host defense mechanisms, leading to frequent clinical or subclinical infections. These repeated infections subsequently activate neuroimmune pathways which lead to the development of IC/BPS symptoms [28, 29]. At this time there is no conclusive evidence to support an

**Table 156.1** Potential mechanisms involved in the pathogenesis of interstitial cystitis.

| Mechanism | Pathophysiologic effect |
|---|---|
| Bladder lining abnormalities | Damage to the bladder protective glycosaminoglycan layer |
| Abnormalities of descending inhibitory pain pathways | Dysfunction in brain centers (or the pathways from these centers) that normally downregulate pain signaling in the spinal cord |
| Neurogenic inflammation | Increased bladder neuropeptide containing nerve endings juxtaposed to increased and activated mast cells, increased urine interleukin (IL) 6 |
| Neurohormonal dysregulation | Dysfunction in the hypothalamic–pituitary–adrenal axis, including higher bladder expression of corticotropin-releasing hormone (CRH) |
| Decreased urothelial repair | Increased secretion of antiproliferative factor (APF) shown to inhibit urothelial cell growth *in vitro* |
| Comorbid conditions | Mechanism unknown; increased rate of psychiatric comorbid conditions, including depression, anxiety, posttraumatic stress, and somatization, as well as allergies, chronic fatigue syndrome, endometriosis, fibromyalgia, irritable bowel syndrome, and inflammatory bowel disease [16, 33] |

Adapted from Theoharides et al. [23].

infectious etiology to IC/BPS, however active infection must be ruled out to make a diagnosis of this condition.

Several other nonmutually exclusive theories that may explain the pathogenesis of IC/BPS have been described in detail and are summarized in Table 156.1. Briefly, immune/neuroimmune mechanisms may have an important role in pathogenesis, including excessive release of neurotransmitters, mast cell-mediated inflammation and morphologic changes in the nerves innervating the bladder. Currently there is no clear evidence of IC/BPS being an autoimmune disease, or being the main etiology for the disease. However, following the recognition of mast cells within the bladder wall of patients with IC/BPS, numerous studies have been published suggesting their role in pathogenesis. Mast cells play a primary role in allergic reactions and acute inflammatory response by recruiting leukocytes, which in turn activate mast cell degranulation [30]. These cells are also involved in angiogenesis, wound healing, bone remodeling, atherosclerosis, and reaction to neoplasm. Multiple components including endocrine, immune, and neurologic pathways are thought to play a role in the pathogenesis of IC/BPS. Activated mast cells play a central role in the activation and signaling of these pathways, linking these cells to the disease process [31]. Although the presence of mast cells and their production of histamine (which causes pain and hyperemia) may provide a reasonable explanation for the disease process, mast cells can be found in the bladder wall of patients without IC/BPS as well as patients with overactive bladder [32].

The bladder epithelium is lined by bladder surface mucin, a continuous layer of proteoglycans and glycosaminoglycans (GAGs). This layer is thought to provide both a permeability barrier to noxious solutes in the urine and a host defense against bacterial adherence. Injury or destruction of the protective layer leads to increased epithelial permeability and susceptibility to infection. Increased mucosal permeability is nonspecific and can be a consequence of bladder inflammation, injury or chemical cystitis, and it may be part of the normal process of aging. Parsons and Hurst hypothesized the concept that IC/BPS in a subset of patients is the result of a defect in the epithelial permeability barrier of the bladder surface GAG [33]. Multiple investigators have demonstrated a link between increased mucosal permeability and GAG layer damage, but whether this represents a primary cause of IC/BPS or merely reflects a secondary event is unclear [33–36]. Furthermore, urothelial dysfunction can also be affected by altered cell adhesions and tight junction proteins [37]. Arguments against the "GAG theory" state that injury to the GAG layer with various invasive treatments including bladder fulguration, bladder hydrodistention, or the intravesical administration of clorpactin or the organic solvent dimethyl sulfoxide (DMSO) may improve bladder symptoms. On the other hand, treatments aimed at "restoring" the GAG layer have a role in the treatment of IC/BPS and will be discussed later in the chapter.

Inflammation, especially if repeated or chronic, can alter tissue innervation, central pain processing mechanisms and tissue response. Neuropeptides present in the spinal cord have an important role in the mediation of nociceptive input, which under pathologic conditions such as inflammation can be altered, leading to functional consequences. Activation of pain fibers can trigger neurogenic inflammation through release of neuropeptides and subsequently increase vascular permeability. Furthermore, mast cell degranulation can be stimulated by neuropeptide mediators, exacerbating inflammation, injury, and increased epithelial permeability. Numerous studies also indicated increased sympathetic activity in patients with IC/BPS [38–40].

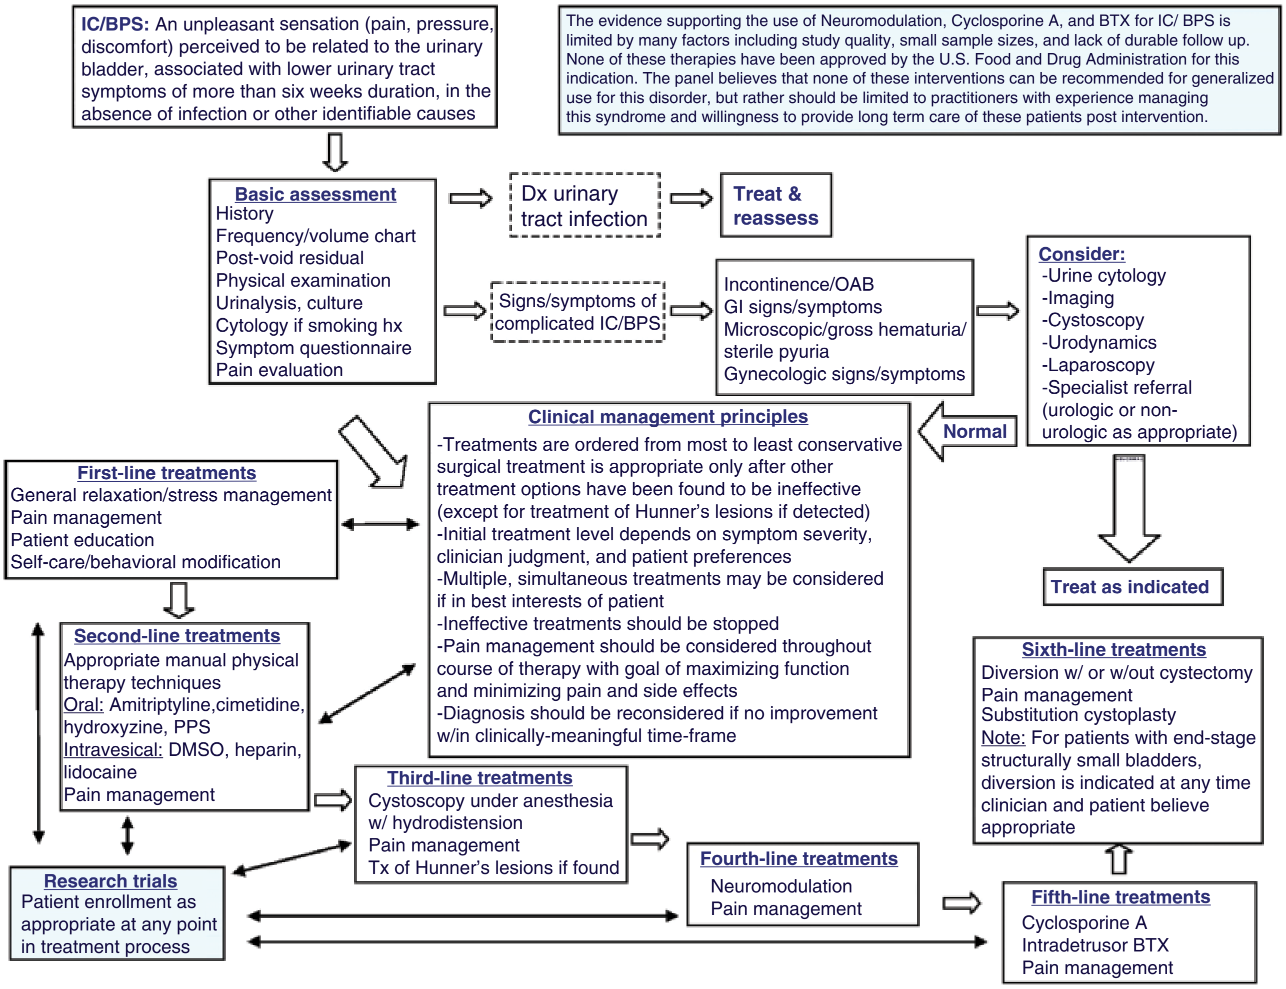
Investigation by Keay et al. into the role of certain cytotoxins involved in epithelial cell damage seen in IC/BPS led to the discovery of antiproliferative factor (APF) [41]. In subsequent studies, the presence of this factor in urine samples was found to be a sensitive and specific biomarker for IC/BPS [42]. The presence of APF significantly decreases levels of heparin-binding epidermal growth factor-like growth factor (HB-EGF), and at the same time upregulates the levels of epidermal growth factor (EGF), which leads to inhibition of primary urothelial cell proliferation [43]. Urine levels of APF, HB-EGF, and EGF reliably distinguish patients with IC/BPS from controls [42]. The presence of APF can also be used to distinguish between men with IC/BPS and those with chronic pelvic pain syndrome/chronic prostatitis [44]. Currently these tests are not commercially available.

## Signs/symptoms and diagnosis

IC/BPS is a clinical diagnosis of exclusion based upon chronic (more than six weeks duration) unpleasant symptoms including pain, pressure, and discomfort perceived to be related to the bladder and associated with lower urinary tract symptoms [2]. The pain usually varies with the degree of bladder distention; hence, urgency and frequency of urination are usually present in an attempt to minimize discomfort [45]. Patients may also complain of pain or pressure throughout other pelvic structures, including the vagina, rectum, and vulva. Urinary tract infection and other potential treatable causes must be ruled out and treated if clinically warranted. Median age of presentation is 40–45 years. According to reports from the interstitial cystitis database, the most common baseline pain sites are lower abdominal pain (80%), urethral (74%), and lower back (65%). Most patients describe intermittent pain of moderate intensity and there have been reports of links between pain sites, urinary symptoms, and worse quality of life [46, 47]. More specifically, suprapubic pain exacerbated by bladder filling has been reported to be a symptom shared by most men and women with IC/BPS [47]. According to a recent study from the MAPP research network the most bothersome single symptom in a cohort of 424 patients with IC/BPS was suprapubic/bladder pain. The women in this cohort did have significantly more bladder-focused symptoms (58%) compared with men (34%) [48]. According to recent prevalence data, between 1.9% and 4.2% of the male population in the United States are estimated to have IC/BPS [49]. There is significant overlap in the symptomatology of IC/BPS and chronic bacterial prostatitis, including suprapubic pain and perineal pain. Sexual dysfunction is also an associated finding, including erectile dysfunction and painful ejaculation.

There is no evidence to suggest that IC/BPS poses a risk of future bladder malignancy; however, it is important to consider underlying malignancy or carcinoma *in situ* in patients over 40 years of age with a smoking history. Other rare conditions, such as eosinophilic cystitis, malacoplakia, scleroderma, schistosomiasis, and detrusor endometriosis, must also be considered. In women, gynecologic problems including endometriosis, pelvic congestion syndrome, and salpingitis can mimic the IC/BPS symptom complex and careful evaluation to rule out any correctable condition should be undertaken. Patients with IC/BPS may also report urinary urgency when queried about whether they normally feel a sudden desire to void. Although these patients may also have simultaneous voiding dysfunction, the urgency felt by IC/BPS is considered to be secondary to pain rather than an impending loss of urinary control [50]. A large-scale survey of individuals diagnosed with IC/BPS showed an unexplained association with other chronic disease and pain syndromes. Allergies, irritable bowel syndrome, and sensitive skin were the most common associated conditions [51]. Furthermore, pain and urgency exacerbations have been documented to occur in small observational reports, especially in periods of high stress [52].

For patients undergoing an initial evaluation, a thorough medical history and evaluation of pain and voiding complaints should be obtained. Pertinent medical history including a description of allergies, history of gastrointestinal, gynecologic, autoimmune, and musculoskeletal disease should be addressed. Symptoms can be evaluated using several validated questionnaires, all of which are designed to assess severity of symptoms. Symptoms scales available include the O'Leary-Sant Symptom and Problem Index, the University of Wisconsin Symptom Instrument, the Global Response Assessment, and the Pelvic Pain and Urgency/Frequency Scale. Although these questionnaires are useful to investigate the severity of symptoms, they do not possess strong diagnostic utility [53]. In addition to characterizing the patient's lower urinary tract symptoms baseline pain symptoms, a physical exam should be performed should be performed including an evaluation of the pelvic floor. Although a presumptive diagnosis can be made based on history and physical examination, further evaluation is necessary to rule out other treatable causes. The 2011 American Urological Association guideline for diagnosis and treatment of IC/BPS provides a comprehensive diagnostic algorithm [1] (Figure 156.2). In addition to indicated laboratory tests, cystoscopy may be performed, however it can be omitted in uncomplicated cases. When indicated, cystoscopy may be used to identify patients with Hunner's lesions, or ulcerative mucosal lesions seen on the bladder urothelium. Biopsies of this area must be performed, as these lesions may resemble carcinoma *in situ* of the bladder. Glomerulations are an additional cystoscopic finding classically described during bladder hydrodistention. Glomerulations are described as submucosal petechiae that have the tendency to bleed once the bladder is emptied after hydrodistention.



IC/BPS: An unpleasant sensation (pain, pressure, discomfort) perceived to be related to the urinary bladder, associated with lower urinary tract symptoms of more than six weeks duration, in the absence of infection or other identifiable causes
The evidence supporting the use of Neuromodulation, Cyclosporine A, and BTX for IC/ BPS is limited by many factors including study quality, small sample sizes, and lack of durable follow up. None of these therapies have been approved by the U.S. Food and Drug Administration for this indication. The panel believes that none of these interventions can be recommended for generalized use for this disorder, but rather should be limited to practitioners with experience managing this syndrome and willingness to provide long term care of these patients post intervention.
Basic assessment
History
Frequency/volume chart
Post-void residual
Physical examination
Urinalysis, culture
Cytology if smoking hx
Symptom questionnaire
Pain evaluation
Dx urinary tract infection
Treat & reassess
Signs/symptoms of complicated IC/BPS
Incontinence/OAB
GI signs/symptoms
Microscopic/gross hematuria/ sterile pyuria
Gynecologic signs/symptoms
Consider:
-Urine cytology
-Imaging
-Cystoscopy
-Urodynamics
-Laparoscopy
-Specialist referral (urologic or non-urologic as appropriate)
Normal
Treat as indicated
Clinical management principles
-Treatments are ordered from most to least conservative surgical treatment is appropriate only after other treatment options have been found to be ineffective (except for treatment of Hunner's lesions if detected)
-Initial treatment level depends on symptom severity, clinician judgment, and patient preferences
-Multiple, simultaneous treatments may be considered if in best interests of patient
-Ineffective treatments should be stopped
-Pain management should be considered throughout course of therapy with goal of maximizing function and minimizing pain and side effects
-Diagnosis should be reconsidered if no improvement w/in clinically-meaningful time-frame
First-line treatments
General relaxation/stress management
Pain management
Patient education
Self-care/behavioral modification
Second-line treatments
Appropriate manual physical therapy techniques
Oral: Amitriptyline,cimetidine, hydroxyzine, PPS
Intravesical: DMSO, heparin, lidocaine
Pain management
Third-line treatments
Cystoscopy under anesthesia w/ hydrodistension
Pain management
Tx of Hunner's lesions if found
Fourth-line treatments
Neuromodulation
Pain management
Fifth-line treatments
Cyclosporine A
Intradetrusor BTX
Pain management
Sixth-line treatments
Diversion w/ or w/out cystectomy
Pain management
Substitution cystoplasty
Note: For patients with end-stage structurally small bladders, diversion is indicated at any time clinician and patient believe appropriate
Research trials
Patient enrollment as appropriate at any point in treatment process

AUA guideline for the diagnosis and treatment of interstitial cystitis/bladder pain syndrome. *J Urol* 2011;185(6):2162–2170. Reproduced with permission of Elsevier.

Hydrodistention is not recommended as a diagnostic or therapeutic procedure because of its adverse effects and low diagnostic yield (low sensitivity and specificity).

Intravesical administration of concentrated potassium chloride, known as the potassium sensitivity test, is still used by some physicians to distinguish the source of pain in women with chronic pelvic pain and possible IC/BPS. The test can be easily performed in the office setting, but may provoke pain and has a low diagnostic value (75% sensitivity) [54]. Another office-based test is the "anesthetic challenge." It is especially useful in patients presenting with acute pelvic pain exacerbations and involves installation of an intravesical anesthetic [55]. Although there is no documentation about sensitivity and specificity, this test is reasonable and can yield useful information about likelihood of bladder-based pain, especially in patients who have a positive response.

## Management

IC/BPS is a complex disease that poses a therapeutic challenge to practioners in various specialties. Even when urinary symptoms are addressed, many patients experience debilitating pelvic pain that is difficult to treat. Recognizing that the etiology of IC/BPS is likely multifactorial, patients are now treated with multimodal and multispecialty approaches to address the different pain components. Lifestyle modifications, pharmacologic therapy, physical therapy, and surgical treatment options are available and often used in sequence or combination to offer patients the best symptom control possible [56].

Patient counseling and education are paramount in the initial treatment of IC/BPS. Patients should be reassured that their symptoms, although bothersome, are not life threatening and that multiple therapies are available.

Behavioral therapy should be introduced to the patient initially as first-line therapy. Pelvic floor retraining, diary keeping, and controlled fluid intake can be utilized in patients with IC/BPS, especially in those with predominant frequency. Expert opinion suggests that maintaining a normal lifestyle and increasing the quality of life for patients with IC/BPS can be achieved with stress reduction, meditation, exercise, massage, and warm tub baths [57]. Numerous complementary and alternative medical therapies have been used in patients with IC/BPS [58]. One randomized controlled study used guided imagery created specifically for IC/BPS patients and compared their pain and urinary symptoms to controls. More than 45% of the treatment group responded with marked improvement on the Global Response Assessment (GRA) and also noted decreased pain and urinary urgency [59]. Acupuncture has been used in patients with IC/BPS and other chronic pain syndromes. Limited evidence exists that it is more effective than placebo and overall results with acupuncture have failed to show long-term efficacy [60, 61].

Dietary modification is another method that can be used to ameliorate symptoms of IC/BPS. Many patients report symptom flares coinciding with intake of certain foods and drinks. Spicy foods and beverages such as alcohol, coffee, and soda are often credited with the onset of symptoms. A recent questionnaire-based study suggested that approximately 90% of IC/BPS patients have food sensitivities [62, 63].

Pelvic floor physical therapy is also a recognized nonpharmacologic treatment for IC/BPS. Physiotherapists guide therapy sessions by applying manual pressure to stretch and compress bundles of muscle fiber, as well as engaging patients in relaxation exercises. When conducted by experienced physiotherapists, pelvic floor myofascial release can achieve up to 70% improvement in symptoms for patients with IC/BPS [64].

Pharmacologic therapy with oral agents often begins with amitriptyline, pentosanpolysulfate sodium, cimetidine, and hydroxyzine [65]. Amitriptyline is a tricyclic antidepressant that has been shown to ameliorate symptoms of IC/BPS when administered in small doses. It has four pharmacologic actions useful for the treatment of IC/BPS: (i) it blocks active transport at presynaptic nerve endings, affecting reuptake of serotonin and norepinephrine, (ii) it has central and peripheral anticholinergic actions; (iii) it blocks H1 receptors and can therefore stabilize mast cells, (iv) it is a sedative. The success rate of amitriptyline is 40–60%, based on small nonrandomized studies. In one large multicenter randomized controlled trial, Foster et al. showed that amitriptyline in conjunction with behavioral modification was not equivalent to placebo when given to amitriptyline-naive patients with IC/BPS. In a subgroup analysis it was demonstrated that patients who achieved and tolerated 50 mg daily had improvements in symptoms [66]. Dose-limiting side-effects include weight gain, constipation, urinary retention, dry mouth, and palpitations.

Pentosanpolysulfate (Elmiron™) is the only US Food and Drug Administration (FDA)-approved agent for the treatment of IC/BPS. The drug is a synthetic sulfated polysaccharide similar to the heparan sulfate analog. Heparan sulfate is one of the GAGs normally found coating the bladder mucosa [67]. Pentosanpolysulfate is thought to be effective in replenishing the defective GAG layer and it has been shown to be a potent inhibitor of allergic and nonimmune mast cell stimulation [67, 68]. Sant et al. conducted a clinical trial to evaluate the safety and efficacy of pentosanpolysulfate. No clinical benefit was observed when pentosanpolysulfate was compared to placebo. In regards to adverse effects, most were noted to be minor and included reversible alopecia, diarrhea, liver enzyme abnormalities, and skin rash. Although this study demonstrated the drug's safety, it was underpowered to make conclusions about efficacy [69]. Parsons et al. performed a randomized controlled trial and found that 32% of the patients treated with pentosanpolysulfate reported significant improvement in comparison to placebo [70]. pentosanpolysulfate was also found to be beneficial in a meta-analysis by Hwang et al., which showed the drug to be more efficacious than placebo in the treatment of pain, urgency, and frequency associated with IC/BPS [71]. The duration of therapy appears to be more important than the dosing. Nickel et al. demonstrated an overall response rate of 50% in dosages ranging between 300 mg and 900 mg at 32 weeks; however, the recommended dosing is 100 mg three times daily for 12 months [72].

Histamine H1 (hydroxyzine) and H2 (cimetidine) antagonists have shown modest therapeutic benefit in the treatment of IC/BPS. H1 receptor blockers are used for their ability to inhibit neuronal activation of mast cells and suppress degranulation. Evidence for the efficacy of hydroxyzine is limited and the maximum benefit demonstrated was a 40% reduction in symptoms [73]. Other trials have found no clinical benefit in symptom improvement [69]. Cimetidine's mechanism of action in IC/BPS is unclear and promising results were found in approximately 66% of patients in one early study [74]. However, follow-up studies showing improvement in suprapubic pain and voiding symptoms were limited by small sample size and lack of histologic evidence to note qualitative change [75].

## Minimally invasive procedures for IC/BPS

### Intravesical agents

The installation of intravesical agents provides an alternative or adjunct to oral therapies as well as a nonsurgical option for patients refractory to conservative treatments. Several agents are available including DMSO, pentosanpolysulfate, chondroitin sulfate, hyaluronan, heparin, and anesthetic agents (lidocaine and bupivacaine). Although the use of intravesical agents is widespread, evidence supporting their efficacy is limited and largely composed of uncontrolled trials [76].

DMSO, a lignin derivative, is the only intravesical agent with FDA approval for the treatment of IC/BPS. DMSO acts as an anti-inflammatory, analgesic, and muscle relaxant [77, 78]. As with many intravesical agents, DMSO is administered weekly for six weeks as a single agent, or as a "cocktail" of several instravesical medications. Reported response rates range from 50% to 90%; however, patients may experience an acute flare-up of pain and irritative voiding symptoms with the initiation of treatment [78, 79]. Common agents used concurrently with DMSO for patients that fail monotherapy include heparin sodium, a steroid (triamcinolone is used in our institution), an antibiotic (gentamicin in our institution), and sodium bicarbonate. Despite the routine use of adjunctive agents, data are limited to support improved patient tolerability and clinical benefit [80]. Side-effects from DMSO include a self-limiting garlic-like odor and taste. The drug is also not recommended for use during pregnancy.

Pentosanpolysulfate, when used as an oral agent, achieves a low bladder concentration, resulting in a long lag time (3–6 months) before clinical improvement can be observed [81]. Davis et al. investigated the drug's safety and efficacy as an intravesical formulation in a randomized trial comparing oral therapy to a combination of oral and intravesical pentosanpolysulfate [82]. Patients who received the combined regimen had a twofold reduction in the severity of IC/BPS symptoms compared with those receiving oral therapy only ($P = 0.4$). Overall quality of life was significantly improved in the combination group, making it a suitable option for moderate to severe IC/BPS. The incidence of adverse events was comparable in both groups.

Intravesical anesthetic agents have an important role in the minimally invasive management of IC/BPS. Local anesthetics are weak bases and therefore absorption is limited in the urinary bladder. Higson et al. first described alkalinization of intravesical lidocaine by administering 40 ml of 1% lidocaine with 40 ml of 8.4% sodium bicarbonate [83]. Henry et al. later showed that alkalinization of urine in the bladder provides safe and predictable lidocaine absorption as well as enhanced anesthetic action, leading to decreased pain scores in patients with IC/BPS [55]. In addition to the well-known action as a local sodium channel blocker, local anesthetics also prevent histamine release from mast cells and function as anti-inflammatory agents. Inflammatory responses are dampened by decreasing the level of certain mediators such as interleukin 1, interleukin 8, and various cytokines [84–86]. The effect of intravesical alkalinized lidocaine was investigated in a randomized trial by Nickel et al. [87]. The multi-institutional study included 102 patients with a diagnosis of IC/BPS. Preliminary results showed the agent to be effective, providing short-term amelioration of symptoms in the majority of patients. The effects lasted beyond the treatment period and no significant adverse effects were reported.

## Endoscopic procedures for IC/BPS

Endoscopic procedures may be indicated during the evaluation and/or treatment of patients with IC/BPS. For patients where cystoscopy is indicated for other reasons (gross, microscopic hematuria) or when initial management steps have been unsuccessful, cystoscopy with bladder hydrodistention may be a useful diagnostic tool. Bladder hydrodistention was first performed in 1922 and eventually became the gold standard to diagnose IC by the 1970s [88]. Findings consistent with interstitial cystitis included reduced anesthetic bladder capacity, presence of Hunner's lesions, and the presence of glomerulations along the bladder mucosa. Hunner's lesions can be distinguished from glomerulations during hydrodistention, as glomerulations become apparent as the bladder is filled. Although these diagnostic criteria still apply today, the utility of hydrodistention has been called into question as a result of studies such as the one performed by Waxman et al., which demonstrated almost half of asymptomatic women in the cohort had cystoscopic findings consistent with IC following hydrodistention [89]. Furthermore, the mechanism for symptom relief is unknown, but theorized to be due to an increased elaboration of bladder surface mucin or a result of temporary nerve injury resulting in incomplete sensory impairment [90]. In our practice, cystoscopy without hydrodistention is performed when there is a concern for Hunner's lesions or if other etiologies have not been excluded.

Bladder hydrodistention is usually performed under general or regional anesthesia. Distension is performed under direct cystoscopic vision to avoid overdistension and mucosal tearing. Distention is limited to short duration intervals of 2–4 minutes at a pressure ranging from 60 to 80 $\mathrm{cmH_2O}$. Glomerulations can often be seen after hydrodistention as punctate submucosal hemorrhages (Figure 156.3). In patients with Hunner's lesions, a biopsy and fulguration should be performed to rule out the presence of malignancy (Figure 156.4). Once a biopsy is performed, bladder hydrodistention is not recommended in the same setting to avoid complications related to bladder perforation and hemorrhage. Finally, consideration should be given to instillation of 20–30 ml of a short-acting anesthetic agent (1% lidocaine), to aid in decreased pain following hydrodistention. For patients

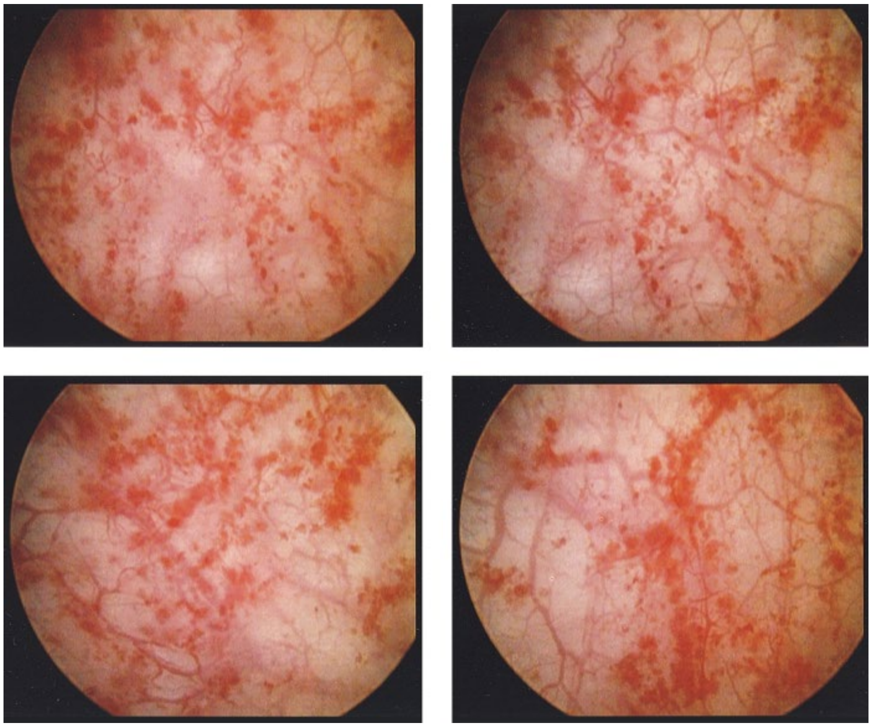


**Figure 156.3** Glomerulations: submucosal hemorrhages seen in interstitial cystitis/bladder pain syndromepatients after hydrodistention.

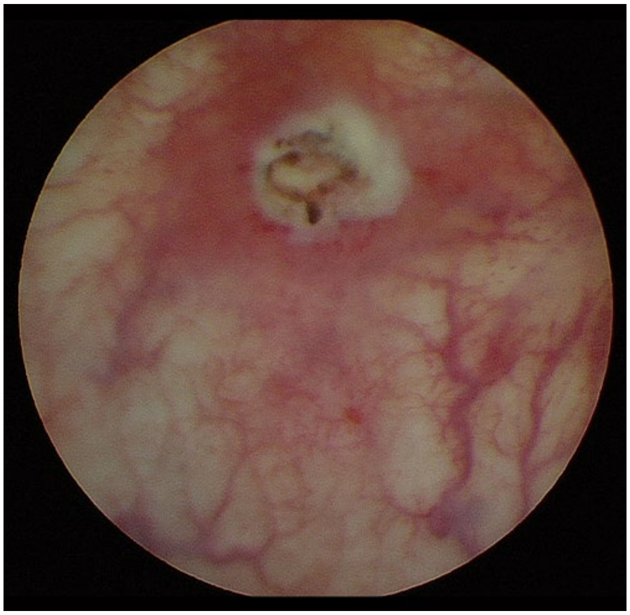

**Figure 156.4** Hunner's lesion after endoscopic fulguration. Note the intense inflammatory tissue reaction that develops upon application of electrocautery.

with severe IC/BPS and small bladder capacity, intravesical installation of hyaluronic acid can prolong the effect of bladder hydrodistention. The number of mean voids per day and bladder capacity were significantly improved for up to nine months in patients receiving hyaluronic acid compared with hydrodistention only or hydrodistention with installation of heparin [41]. Intradetrusor injection with botulinum toxin A (reviewed below) has been reported in setting of hydrodistention, with a 25% reduction in urinary frequency and overall response rate found to be 74% [91].

Intradetrusor injections with botulinum toxin type A (BTX-A) and submucosal injection of triamcinolone acetonide represent the most invasive of the intravesical agents used in IC/BPS. In general, BTX-A is used for the treatment of muscle overactivity and spasticity of various diseases. With regard to urologic disease, BTX-A is FDA approved for neurogenic detrusor overactivity and overactive bladder. BTX-A has also been used off-label in the treatment of IC/BPS, owing largely to its analgesic properties that have been shown to impede the release of neuronal signals such as substance P and glutamate [92]. Giannantoni et al. showed that intravesical injection is effective for the short-term management of refractory painful bladder syndrome [93]. Patients received 200 U of BTX-A diluted in 20 ml of 0.9% sodium chloride, using a rigid cystoscope and a flexible needle. A total of 10 U were given per injection site and injections were administered to the lateral wall and trigone. This group demonstrated significant improvements in daytime and night-time frequency, and improved bladder capacity was noted on follow-up cystometry. However, a significant number of patients required clean intermittent catheterization to manage short-term detrusor hypocontractility. Others have reported satisfactory efficacy; with injections of 100 U of BTX divided into 10 sites in the trigone no patients experienced voiding dysfunction [94]. Furthermore, Smith et al. reported their experience with BTX for IC/BPS patients, with 71% of patients having significant improvement in Cystitis Symptom Index score [95]. BTX has been used in the setting of bladder hydrodistention to reduce postprocedure pain. Liu and Kuo treated patients with 100–200 U of intravesical BTX followed by hydrodistention [91]. Treatment was considered successful if patients reported an improved quality-of-life index, complete resolution of bladder pain, and absence of voiding dysfunction. Partial response was recorded for patients with improved quality-of-life index, reduced pain (reduction of >2 points on the pain scale), and a greater than 25% reduction in urinary frequency. Patients reported symptomatic improvement at three months and the overall response rate was 74%. In addition to intradetrusor injections, BTX injections of the pelvic floor have been used in patients with a significant pelvic pain component secondary to myofascial dysfunction [96].

### Endoscopic management of Hunner's lesions

Hunner's lesions are found in approximately 5–10% of patients with IC/BPS. Patients in this subgroup tend to experience greater urinary frequency and are found to have smaller bladder capacities. Although these patients present with severe symptoms refractory to conservative management, endoscopic management using fulguration or resection techniques offers a durable therapeutic option. In the setting of a new diagnosis of a Hunner's lesion, a biopsy is recommended in order to rule out carcinoma *in situ* of the bladder.

Transurethral resection of Hunner's lesions and surrounding mucosa has been investigated by several retrospective studies. Peeker et al. reported an analysis of 103 patients with Hunner's lesions who underwent a total of 259 transurethral resections of visible lesions. Ninety-two patients reported improvement of symptoms, and 40% of this group had a durable response lasting beyond 3 years. In addition, they found that patients with a diminished bladder capacity demonstrated the poorest response to treatment [97]. Although transurethral resection has been shown to be safe and effective, there remains the theoretical risk of bladder perforation and scarring. As a result, fulguration of Hunner's lesions has become the preferred method of endoscopically managing Hunner's lesions. Fulguration can be performed using a Bugbee electrode, rollerball, or monopolar or bipolar loop. In our institution we prefer to use the Bugbee electrode, set at 30 V. Endoscopic fulguration has been shown to be an effective procedure, but many patients may require repeat interventions to achieve a durable response. Hillelsohn et al. found that 45.8% of patients required repeat fulguration within 4 years of treatment [98]. Despite a high reintervention rate, bladder fulguration is still a reasonable therapeutic option. In a recent study, Chennamsetty et al. retrospectively analyzed a cohort of 76 patients who underwent 214 endoscopic fulgurations, where 89% of patients noted some degree of improvement in symptoms and 98% would undergo the procedure again [99]. Furthermore, they found that bladder capacity was not significantly decreased by undergoing multiple procedures.

Laser ablation of Hunner's lesions is an endoscopic alternative to fulguration; however, there are no clinical trials available to compare the efficacy of each method. In one early study using a neodymium:YAG (Nd:YAG) laser over half of the cohort reported a therapeutic benefit. However, two small bowel perforations occurred during the study, thus limiting its widespread use. Laser ablation was revisited by Rofeim et al., who performed a prospective study in a cohort of 24 patients and a follow-up of 23 months [100]. Low-energy (10–15 W) settings were used to ablate visible lesions and limit the depth of penetration to 5 mm. Within 2–3 days of the procedure, patients reported a decrease in pain, frequency, and urgency. Fifty percent of patients required only one treatment and had a mean response of 19 months. There were no significant complications, including bladder perforation or bowel injury, likely due to attempts to avoid bladder distension.

Endoscopic steroid injection of Hunner's lesions can serve as an alternative to fulguration techniques in the management of Hunner's lesions. The theoretical advantage of steroid injections is the potential of successfully managing Hunner's lesions without the associated complications, resulting in scarring or bladder perforation. Cox et al. performed a prospective study utilizing triamcinolone acetonide injections directly into Hunner's lesions [101]. They performed injections under general anesthesia, and injected 10 ml of triamcinolone acetonide (40 mg/ml) divided into 0.5 mL injections per site (Figure 156.5). Their results showed that 28/30 (93%) of patients reported improvement in urinary symptoms, while 21 (70%) reported much improvement. In our institution we utilize doses as low as 30 mg with similar results with regard to irritative urinary symptoms related to Hunner's lesions.

## Conclusions

The diagnosis and management of IC/BPS remains challenging for both patients and practitioners. For most patients, medical management remains the cornerstone of the treatment plan. However, for patients who fail medical management or those who have predominantly

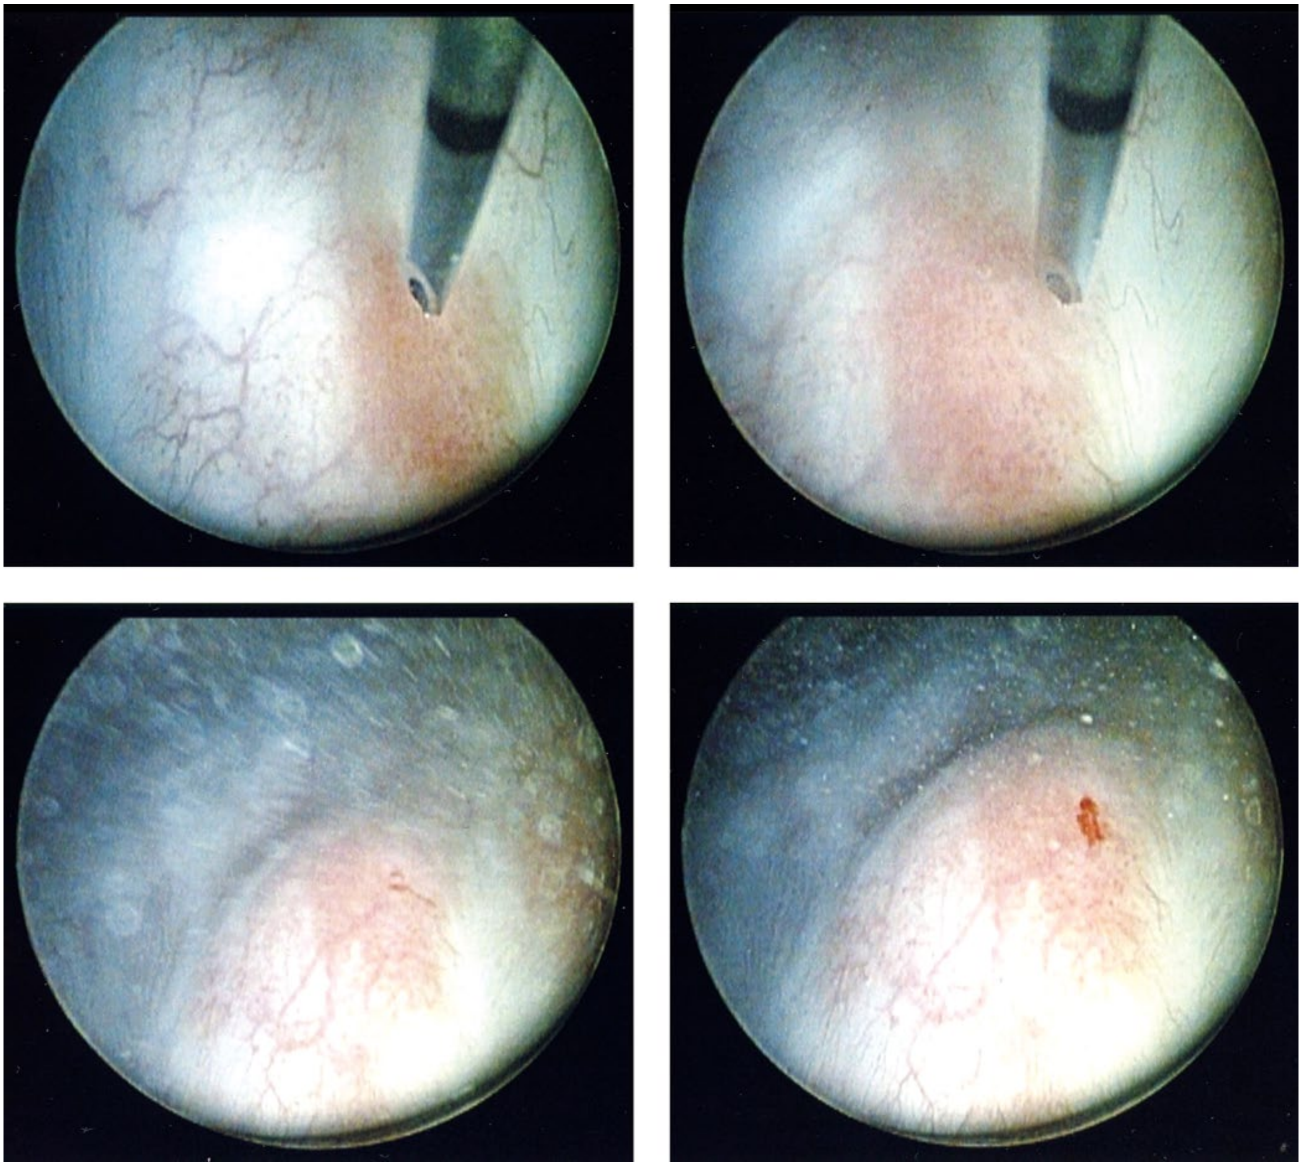

**Figure 156.5** Submucosal triamcinolone acetonide injection. Note how the needle bevel is positioned towards the bladder lumen so that a submucosal wheal is formed.

bladder pain symptoms, minimally invasive techniques are a safe and effective way to manage IC/BPS. Future directions to better characterize symptoms and effectively treat patients with IC/BPS are being investigated and will surely fill a void in this urologic condition.

## Introduction

Bladder cancer is the second most commonly diagnosed urological malignancy. The incidence and prevalence of bladder cancer in western as well as in developing countries continue to rise [1]. Although it is not the most frequent malignancy, bladder cancer's high recurrence and progression rates, as well as its long disease-specific survival rate, makes the treatment for bladder cancer far more costly than that for other cancers, such as rectum, lung, and prostate [1]. In addition, because of the high recurrence rates, follow-up procedures such as cystoscopies with biopsies and intravesical chemotherapy also contribute to the high costs [1]. Thus the primary aim of surgical and nonsurgical treatment strategies are to optimize the outcomes and reduce the secondary interventions.

The majority of patients with bladder cancer are diagnosed with a nonmuscle-invasive bladder cancer (NMIBC). Most of these are candidates for transurethral resection of bladder tumor (TURBT), with conventional monopolar transurethral resection of the bladder being the gold standard for this operation. Complete and radical tumor removal during TURBT is essential for initial diagnosis and follow-up strategy planning [2].

There are diagnostic, surgical, and oncologic limitations to the contemporary technology and techniques used for conventional TURBT. The main diagnostic issue is the absence of the detrusor layer in the pathology after TURBT. Without the presence of the muscle layer, pathologists are often unable to correctly define pT stages of bladder cancer. The second most common diagnostic issue is thermal damage to the specimens, which can significantly affect pathological results. As a result of these drawbacks, low-quality pathologies may require a second-opinion pathologist consultation, and additional costly immunohistochemical investigations [3]. Surgical disadvantages of conventional TURBT include bladder perforation, obturator nerve stimulation, bleeding, and ureteral ostium injury during or after the surgery. Although the complication rate of monopolar TURBT is low, for high-risk patients there could be surgical and safety issues.

The oncological outcomes for any cancer procedure are major limitations. Piecemeal resection of the lesion ignores the parameter of negative surgical margins, leaving behind positive margins and viable cancer cells with potential for recurrence and metastasis. This approach also allows tumor cells to migrate into the irrigation fluid, which facilitates their implantation and early recurrence. Another issue is the possibility that tumor cells may disseminate into paravesical fat in the case of perforation [3].

In order to improve conventional TURBT, a "non-piecemeal-resection" endoscopic technique was developed with the aim of optimizing treatment results. The technique consists of entire (*en bloc*) tumor endoscopic removal by means of a loop and hook-shaped or J-shaped electrode. Initially, this technique did not gain widespread popularity because of the technical limitations of endoscopes and monopolar generators. However, with recent improvements and developments in monopolar and bipolar electrosurgery, the introduction of vaportrodes, holmium laser devices, and water jet technology, the *en bloc* tumor removal technique has been revisited.

The purpose of this chapter is to provide an overview of the current state of the *en bloc* technique, the surgical technique and technology used, patient selection

strategies, indications and contraindications for the *en bloc* procedure, the feasibility of immediate intravesical chemotherapy, and postoperative follow-up and catheterization time.

## Technique of *en bloc* bladder tumor removal (see Video 157.1)

The procedure is initiated with induction of general anesthesia and positioning the patient in dorsal lithotomy position.

### Step 1

The bladder is thoroughly and systematically inspected by rigid or flexible cystoscope, using bladder mapping. If the technology is available, photodynamic diagnosis, narrow band imaging, or computer virtual chromoendoscopy will significantly enhance tumor size detection and facilitate the identification of satellite sessile tumors [4, 5].

### Step 2

Once the tumor has been detected and evaluated, the bladder mucosa, submucosal layer, and muscle layer are dissected (all at the distance of 0.5–1 cm) around the tumor base, with monopolar (bipolar) loops, a hook-shaped (J-shaped "sand-wedge," Figure 157.1) electrode, or an end-firing laser fiber. All visible bleeding blood vessels are simultaneously coagulated. The tumor is circumferentially resected together with the base and separated from the bladder wall. The separation technique is different. When "frontal energy" is used (hook or J-shaped electrodes, end-firing laser fibers) the separation movement are like axe cuts; when "circular energy" is applied (circle or bent loops, Figure 157.2), the movements are similar to those used when sawing a tree.

Next, electrocautery (laser energy) is used to burn and seal the blood vessels.

Water jet technology has an additional step. A flexible hole probe (hybrid knife) penetrates the mucosa around the tumor base into the level of the resection margin. Water is pumped through the probe under the tumor base to elevate the tumor, and then the tumor is carefully resected in one piece with the base by the same instrument (Figure 157.3).

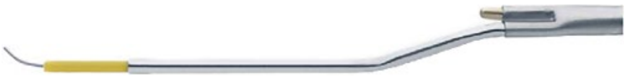

**Figure 157.1** Sand-wedge electrode.

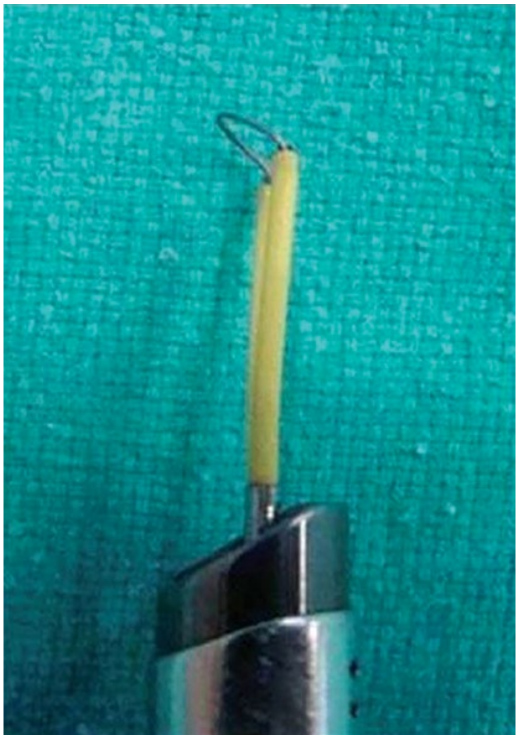

**Figure 157.2** Bent loop.

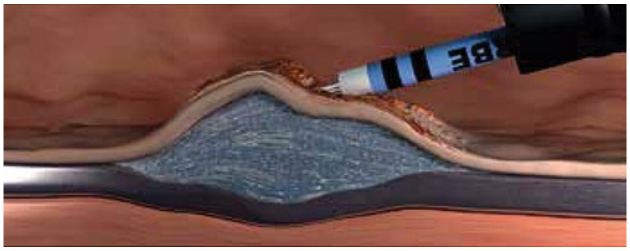

**Figure 157.3** Waterjet hybrid knife tissue elevation and dissection.

### Step 3

Following resection of the tumor, resected specimens are actively aspirated through the sheath. Alternatively, tumor pieces can be removed using different forceps (baskets, extractors, etc.) (Figure 157.4). When large tumors are presented, specimens can be divided into smaller sections by conventional resectoscope loop and then removed.

### Step 4

Once the tumor has been removed, the resected area is checked for bleeding, possible perforations, or residual tumors. Photodynamic diagnosis, narrow band imaging, or chromoendoscopy can be used to enhance intraoperative visualization of the resection margin and detect tiny satellite papillary tumors.

### Step 5

The final step of endoscopic operation for bladder cancer is postoperative chemotherapy instillation. If there is no severe bleeding or perforations, chemotherapeutic drugs can be instilled via a catheter immediately after instrument removal from the bladder.

Energy sources that are used for *en bloc* resection are listed in Table 157.1.

## Discussion

Ukai et al. from Japan reported using a J-shaped needle electrode to remove bladder tumors and Kawada et al. reported the use of *en bloc* resection for a 2.5 cm papillary tumor in 1997 [3, 6]. Three years later, in 2000, Ukai and authors published their own experience of *en bloc* resection, using a J-shaped needle monopolar electrode to make a circumferential incision around the tumor that also included a 5 mm safety margin [3]. The first step of the procedure was to make a blunt dissection from the line of incision. After the tumor was detached, it was removed using either a syringe or, in the case of large pieces, a laparoscopic retrieval bag [7]. The technique of cold-cup biopsies to insure complete tumor removal was also described by some authors [8–10].

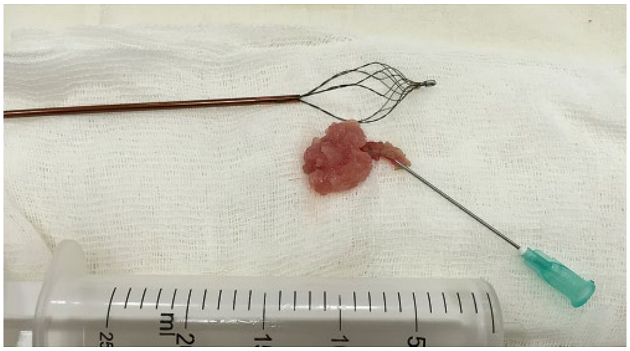

**Figure 157.4** Extractor and removed tumor.

The use of holmium:YAG (Ho:YAG) laser for transurethral *en bloc* resection of bladder cancer was first published by Saito, who concluded that it was a safe and useful technique for pathological evaluation [8]. Wolters et al. published a paper using a thulium laser for *en bloc* tumor resection. They were able to demonstrate detrusor muscle in all six cases, showing that it was possible to achieve exact staging at the time of primary transurethral operation [9]. Nagele et al. proved the feasibility of waterjet-induced resection to safely remove bladder tumors [10] and Fritsche et al. presented the first prospective clinical trial of waterjet-induced resection [11]. In addition to finding the application to be safe and applicable for *en bloc* dissection, they also reported feasibility in tumor sizes up to 7.5 cm. These authors [10, 11] first injected saline into the submucosal layer under the tumor base. After the tumor was elevated from the bladder wall, it was then safe to use *en bloc* resection. The results of numerous published data are shown in Table 157.2.

The data in Table 157.2 clearly show that the ideal tumor size for *en bloc* removal ranges from 2 to 4 cm, and the recurrence rate varies between 15% and 37%.

**Table 157.1** Instrumentation for *en bloc* transurethral bladder resection.

| Energy source | Resection device | Pro | Cons |
|---|---|---|---|
| Monopolar | Angled or flat loop<br>Hook electrode<br>Sand-wedge (J-shaped) electrode | Easily switched to transurethral resection<br>No additional costs<br>Many urologists are familiar | Obturator reflex<br>High perforation risk<br>Transurethral resection syndrome<br>Thermal pathology injury |
| Bipolar | Rectangular longitudinal loop<br>Hook electrode<br>Button (mushroom) electrode | Patients with pacemakers, metal prosthesis<br>No transurethral resection syndrome<br>Less thermal pathology damage | Urethral stricture? |
| Waterjet (hybrid) | Hybrid knife | No or diminished perforation risk<br>Good quality of pathology | Need for additional instruments for biopsy<br>Relatively new technique |
| Ho:YAG | Laser fiber | Bloodless technology<br>No pathology injury<br>No obturator reflex<br>Diminished perforation risk | High cost<br>Time-consuming technique |
| Tm:YAG | Laser fiber | The same as Ho:YAG<br>Faster than Ho:YAG | High cost<br>No long-term data |

**Table 157.2** Results of *en bloc* tumor resection.

Although many papers have looked at the efficacy and safety of *en bloc* resection, only a few publications have relatively large samples. Kramer et al. is currently the largest study in this particular field, with 221 patients enrolled at six academic hospitals in this European multicenter study [16]. Using monopolar/bipolar current or holmium/thulium laser energy, the results of this study found that *en bloc* resection of bladder tumor is a safe and reliable procedure, and provides high-quality resections for tumors >1 cm.

### Laser *en bloc* resection

Zhu et al. compared holmium laser resection with standard TURBT in nonmuscle-invasive bladder cancer [17]. The results revealed no difference in recurrence-free survival between the techniques. The laser group had fewer perioperative complications, and was deemed better in terms of safety and pathology quality. Xishuang et al. further evaluated the safety and efficacy of holmium laser transurethral bladder resection, comparing it with conventional monopolar and plasmakinetic techniques [14]. They found that the complication rate, catheterization, and hospitalization times were superior in both bipolar and holmium laser arms; recurrence rates were equal in all groups.

Another type of laser in *en bloc* resection is the thulium laser (Tm:YAG), a 2 μm laser used for nonmuscle-invasive bladder tumor treatment. A study done by Zhong et al. evaluated the safety and efficacy of a 2 μm continuous wave laser compared with holmium laser and standard transurethral resection. The retrospective study, which included 97 patients, found there was less hemoglobin drop in the 2 μm laser groups; the recurrence rate of all groups showed no statistical significance [18].

In contrast with electrosurgery, which uses a 26 Fr resectoscope, laser resection with a flexible cystoscope is more feasible. Laser resection may be a preferable option in patients with hip joint ankylosis who cannot be placed in lithotomy position. Ho:YAG and Tm:YAG lasers have wavelengths of 2100 and 2013 nm, respectively, and both use water as chromophore. Both these lasers also provide fast and high-power tissue vaporization, and obtain excellent hemostasis. However, the thulium laser produces a smoother cutting line and provides more precise incision than the holmium laser. Zhong et al. advocated that thulium laser resection is superior over electrosurgical techniques in cases when the tumor is located in the bladder neck, or in the bladder dome due to lower perforation risk [18]. Another clinical advantage of laser *en bloc* technique is the absence of obturator nerve stimulation; thus there is no risk of bladder perforation while performing resection on the lateral wall.

## Pathologic considerations

Ukai et al. demonstrated that transurethral resection in one piece (TURBO) can act as an accurate pathological staging tool for bladder cancer [12]. Seven (7%) patients with tumors with deep resection margins positive for carcinoma were assigned an ambiguous pathological stage ("pT1 or higher" or "pT2 or higher"). Five of those patients had tumors with muscle invasion, which can provide a potential reason for the use of therapeutic decision-making, such as performing a radical cystectomy. The remaining two cases have tumors staged as pT1 or higher due to the absence of the muscularis propria. This might represent a limitation of the *en bloc* technique. However, a major advantage of this technique is that urologists can obtain good-quality tumor specimen, which would ultimately lead to superior histopathological diagnosis and accurate pathological staging.

Using the *en bloc* technique, the step-sectioned strips of the entire tumor specimen are amenable to precise histological evaluation of the entire *en face* sections, and the complete interface between the tumor base and the lamina propria. This allows much easier and more definitive discrimination between pTa and pT1 stages. In addition, pathologists can reliably estimate the distance between the invasive front and the resection margin, which can be a potential indicator of histologically proven complete resection. In certain cases with divisional resection, accurate pathological staging was possible when the tumor's topography was exactly reconstructed before resection, though the accuracy of the staging might be lower than for tumors resected in an *en bloc* manner. An important aim of TURBT is to obtain high-quality tumor specimens. It is important to note that those obtained by conventional transurethral resection are inevitable fragmented and poorly oriented.

In assessing the depth of invasion, the only reasonable statement is "stage T1 at least" in the case with lamina propria invasion, or "stageT2 at least" in the case with muscle invasion [19]. The use of clinical staging (Ta or T1) instead of pathological staging (pTa or pT1) is recommended when conventional transurethral resection is performed [20]. In this regard, *en bloc* resection provides tissue specimens adequate for pT categorization because the tumor and surrounding structures are mostly preserved. The presence of the musclaris propria in tumor specimens is crucial for accurately discriminating between stages pT1 and pT2 [21].

In a substantial number of cases, transurethral resection specimens lack the muscularis propria. Herr and Donat showed that 40% of T1 tumors did not have muscularis propria in the specimens [19], while Maruiniak et al. reported the absence of the muscularis propria in 51% of cases [20]. The lack of the muscularis propria in TURBT specimens is more likely to lead to understaging, resulting in misled therapeutic decisions. In the study by Ukai et al., the *en bloc* specimens included the muscularis propria beneath the tumor base in 82% of the cases [12]. *En bloc* technique then might have an additional advantage because we used a technique involving dissection, primarily into normal-appearing tissues under direct vision. Of the 17 patients (18%) whose tumor specimens did not include any obvious muscle issues, 15 patients had tumors that were staged as either pTa or pT1 when negative resection margins were present. Thus, pathological stages were assigned to the tumors in 93% of the patients undergoing *en bloc* resection.

In order to overcome the limitations of TURBT, several authors recommend a second-look transurethral resection for all T1 tumors, multiple high-grade Ta tumors, and all cases including carcinoma *in situ* [22]. Kolozsy reported that 36% of T1 tumors are incompletely resected and that the most common site of residual tumor (26%) was the floor of the resection [23]. Grimm et al. showed that residual tumor was found in 33% of all repeat resection cases, and in 81% of the cases at the initial resection site [24]. Although repeated transurethral resection does not completely eliminate the risk of residual tumor, Ukai et al. found that the *en bloc* technique is a potential tool to replace or even surpass the role of repeated resections [12]. Their follow-up results showed that the overall 5-year recurrence-free rate was 55%, with only one patient (1.2%) having progression to muscle-invasive disease [12]. These high positive results following *en bloc* resection might be attributed to the possibility of residual tumors at the resection floor, even though superficial recurrences from invisible residual tumor might occur at the border of the resection area or elsewhere. Often, it is arduous to entirely remove a poorly demarcated tumor even with *en bloc* technique, especially in cases with associated carcinoma *in situ*. Extreme caution is then needed in evaluating the usefulness of *en bloc* resection, considering there was a selection bias in Ukai et al. study, and a medium follow-up of 27 months is too short to draw any conclusions regarding tumor recurrence and progression [12].

## Limitations

*En bloc* methods also have some limitations. First, there are some technical difficulties compared with conventional resection, such as more resection time, depending on the size, volume, location, and multiplicity of the tumor. Ukai et al. assumed that tumors that are visible and can be completely resected by traditional resection, can also be successfully resected by one piece [12]. Second, Naselli et al. [7] had to divide a large tumor into smaller portions in order to collect it through a resectoscope sheath. Occasionally, it might be difficult to collect a tumor specimen whose largest dimension is substantially larger than the caliber of the resectoscope sheath. The tumor is subject to divisional resection, not because it cannot be resected *en bloc*, but because it is required to be retrieved through the resectoscope sheath. The divisional resection deteriorates the quality of the specimen to varying degrees, but even divided tumor specimens might be better material for pathological evaluation than fragmented chips after resection. Finally, pathologists cannot histologically confirm the completeness of the resection, even though visually complete resection was performed. A resection can be qualified as histologically complete when all margins, including deep and lateral, are negative for carcinoma (Figures 157.5 and 157.6). However, the assessment of every lateral margin in all stepped sections is not always possible, due to denudation of the crush and thermal artifacts of the circumferential epithelium [12]. To overcome these limitations,

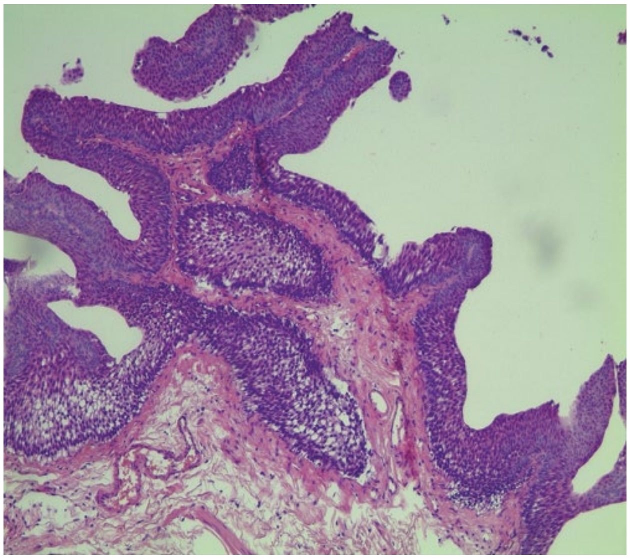

**Figure 157.5** Tumor margin can be clearly seen.

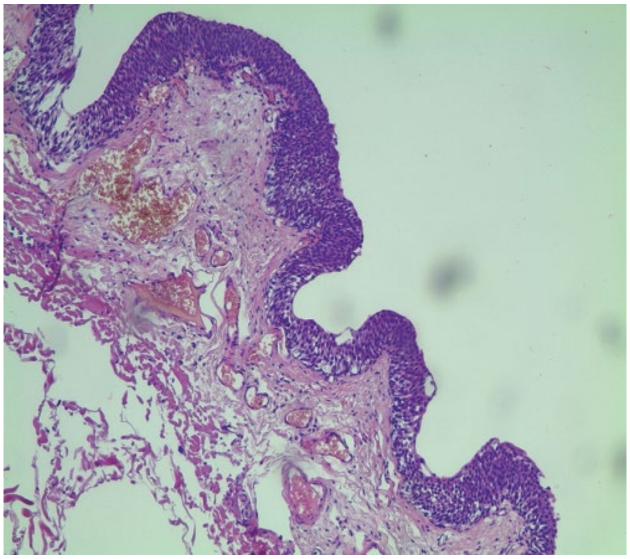

**Figure 157.6** Negative surgical margin (normal urothelium).

improved methods of one-piece resection and collection, yielding high-quality specimens (with a high success rate) should be further studied.

## Complications

The complications rate for *en bloc* resection is low, as the complications for the procedure are similar to those of conventional transurethral resection. All available data concerning possible complications of *en bloc* resection are listed in Table 157.3. In addition to describing the complications, all recent publications classified them according to the Clavien–Dindo system, which focuses on the morbidity and influence of treatment results. Possible explanations for the relatively low complications rate include: (i) *en bloc* technique was performed by only experienced endourologists, while routine transurethral resection was usually done by young, inexperienced residents; (ii) indications for *en bloc* technique include solitary or multiple (less than 4) tumors between 2 and 4 cm in size, which are normally free of complications; and (iii) laser and waterjet technologies have fewer complications than conventional electrosurgery.

**Table 157.3** Complications of *en bloc* resection.

| Series, year | No. of patients | Tumor size (mm) | Complications |
|---|---|---|---|
| Lodde, 2003 [25] | 37 | <25 | Bladder perforation – 1 |
| Saito, 2001 [8] | 35 | <25 | No complications |
| Nagele, 2011 [10] | 5 | <20 | No complications |
| Fritsche, 2011 [11] | 17 | 4–75 | No complications |
| Zhu, 2008 [17] | 96 | <20 | Bladder perforation – 1 |
| Xishuang, 2010 [14] | 64 | <36 | Ureteral orifice stricture – 1 |
| Zhong, 2010 [18] | 55 | <30 | No complications |
| Yang, 2009 [26] | 9 | <30 | Bladder perforation – 1 |
| Gao, 2009 [27] | 32 | <30 | No complications |
| EBRUC, 2015 [16] | 221 | <50 | Clavien ≥3, $n = 6$ |
| Martov, 2016 [28] | 106 | <30 | Clavien ≥3, $n = 2$ |

The low complications rate of the *en bloc* technique in all cases guarantees the option to do immediate chemotherapy instillation, which drastically improves treatment results.

## Oncological efficacy/influence on progression and recurrence

Data from various *en bloc* studies concerning recurrence and progression rates are shown in Table 157.4.

The recurrence rate of nonmuscle-invasive bladder cancer after *en bloc* tumor removal is approximately 30–40%, while the progression rate is 16%. Two monopolar studies have compared *en bloc* tumor removal with conventional transurethral technique. In the first, Lodde et al. reported 36.4% recurrences for transurethral resection [25], and in the second, Ukai et al. reported 37% recurrences [12]. Tumor progression was observed in six cases (16%) in Lodde's study, and there were no data on adjuvant intravesical chemotherapy. Postoperative

**Table 157.4** Recurrence and progression rates of bladder cancer after en bloc resection.

| Authors, year | Stage T | Grade G | Follow-up, months | Recurrence/progress | Instillation chemotherapy |
|---|---|---|---|---|---|
| Lodde, 2003 [25] | Ta = 51,<br>T1 = 11 | G1 = 43<br>G2 = 10<br>G3 = 9 | 10–24 (14) | 12 (36%)/<br>6 (16%) | No data |
| Ukai, 2010 [12] | Ta = 30<br>T1 = 58<br>T2 = 2 | G1 = 3<br>G2 = 46<br>G3 = 48 | Up to 84, medium 27 | Rec 30 (37%) | 46%, then 27% BCG |
| Xishuang, 2010 [14] | Ta = 36<br>T1 = 23<br>CIS = 5 | G1 = 22<br>G2 = 35<br>G3 = 7 | 24 | Rec 20 (31.7%) | Mitomycin in all cases |
| Zhong, 2010 (Ho:YAG arm) [18] | Ta = 19<br>T1 = 5<br>CIS = 1 | G1 = 10<br>G2 = 15<br>G3 = 0 | 24 | Rec 6 (24%) | Epirubicin in all cases |
| Zhong, 2010 (Tm:YAG arm) [18] | Ta = 23<br>T1 = 5<br>CIS = 2 | G1 = 6<br>G2 = 24<br>G3 = 0 | 24 | Rec 8 (26.7%) | Epirubicin in all cases |

chemotherapy was used in 46% cases of transurethral resection and, in cases of recurrence after chemotherapy, was followed in 27% cases by BCG immunotherapy. In Ukai's group, there was no difference in recurrence risks between pTa and pT1 arms [12]. The medium follow-up time was 27 (3–84) months, which was twice as long as in Lodde's study. The recurrence-free time was 77% after 1 year, 63% after 3 years, and 55% after 5 years [29]. The authors marked pT1G3 with the presence of carcinoma *in situ* at the re-evaluation of the initial pathology in one patient whose disease progressed.

Fritsche et al. evaluated recurrence and progrssion rates in waterjet *en bloc* tumor removal [11]. The study included 13 patients with nonmuscle-invasive bladder tumors, in 3 (23%) of which recurrences were found and in 1 case tumor progression. Maximum follow-up was 14 months.

The recent holmium laser technique is described in the works of Zhu et al. [17] and Xishuang et al. [14]. Zhu's group compared holmium laser *en bloc* resection with conventional transurethral resection, and they found similar recurrence rates after both techniques. The average follow-up time was 34 (18–43) months. Xishuang et al. conducted the same study design, and their results between the techniques were statistically insignificant, aligning with the data from Zhu et al. [14]. Zhong et al. conducted a three-arm study comparing conventional bladder resection with thulium and holmium bladder *en bloc* resection [18]. They found the recurrence rates to be 30.95%, 26.67%, and 24.00%, respectively; however, differences were also statistically insignificant. In another study, Wolters et al. showed no pathological recurrences in second-look transurethral bladder resection six weeks after initial thulium *en bloc* bladder removal (4 patients) [9]. The study done by Gao et al. revealed 3 recurrences out of 9 at the area of previous surgery in a group of 32 patients. The overall accumulated recurrence rates were 9% at three months, 22% at six months, and 28% at 12 months. There was no stratification on pT criteria in this study [27].

In a recent study by Muto et al., out of the 55 patients who underwent thulium *en bloc* resection, only one patient had progression with initial pT1G3 [15]. The recurrence rate was 14.5%, with the average follow-up being 16 months (8–25). Second-look cystoscopy was performed in 30–90 weeks for all cases. The authors also noted that all recurrences were found outside the place of previous resection [15].

In the En Bloc Resection of Urothelium Carcinoma of the Bladder (EBRUC) trial, 148 patients were followed for 12 months, and 33 (22.3%) had recurrences. Of those recurrences, 63.6% occurred outside of the *en bloc* resection field, and no statistical difference was noticed between electrosurgical and laser arms [16]. In our recent study, the recurrence rate was 21% (18/86 patients), and all cases were outside the previous surgery site; there were no cases of tumor progression [28].

Based on the results of the current literature, clearly there is a need to evaluate the potential oncologic benefits of the *en bloc* technique. This supports the notion that further examination of this technique is needed, with methods adhering to ubiquitous oncologic principles not followed by the conventional transurethral bladder procedure.

## Conclusions

Approximately 75–85% of bladder cancer patients present with disease confined to the mucosa (pTa, carcinoma *in situ*) or submucosa (pT1). The absence of detrusor muscle in the pathology is associated with higher risk of residual disease and early recurrence. The exact pathological staging of bladder cancer is crucial for the strategy in disease treatment, and complete and accurate removal is essential to achieve good prognosis in the disease management. TURBT with conventional wire loop is still the gold standard treatment for nonmuscle-invasive bladder cancer. Despite several clinical and diagnostic drawbacks, the most important are the oncological disadvantages (tumor resection instead of *en bloc* removal) of the conventional transurethral technique.

Recent advances in endourology have led to the introduction of a range of novel *en bloc* methods that allow bladder tumor to be removed in one piece. For example, different shaped loops and electrodes have been created to facilitate tumor removal, and many new techniques have been evaluated to safely and promptly remove detached tumors from the bladder. These include, but are not limited to, monopolar, waterjet, bipolar, holmium and thulium laser techniques, and every year, more new clinical advancements are announced. This reflects the strong clinical importance of this issue. Although there is a surge of interest pertaining to *en bloc* methods, there is a lack of statistically significant data from properly designed studies. Because of this, these techniques are still under evaluation from clinical and oncological points of view.

Well-established advantages of *en bloc* bladder tumor removal include good-quality pathology specimen with the possibility of macroscopic tumor description, the possibility to evaluate surgical margins, and the presence of both the detrusor muscle and lamina propria muscularis. These advantages allow pathologists to better detect pT and G. Last but not least, an advantage of the *en bloc* technique is the ability to substratify pT1 into pT1a, pT1b, and pT1c due to the presence not only of the detrusor layer but also the lamina propria muscularis of the mucosal layer. Thermal damage to the specimen occurs less often compared to conventional piecemeal tumor resection because the resection area is smaller.

The typical size for *en bloc* resection is between 1 and 3 cm. If the tumor is smaller, it could be easily resected in one cut with conventional wire loop, though many authors advocate the *en bloc* technique in such cases because of the high probability of tumor thermal damage during resection. The upper limit of 3 cm for *en bloc* tumor removal is linked to the difficulty of tumor removal from the bladder in case of larger pieces. Despite the existence of several techniques and tricks to overcome these difficulties, it is much easier to resect larger tumors according to conventional resection rules. However, in some series, the upper limit for *en bloc* removal is 5 or even 7.5 cm. The additional advantages of staying within the limits of 1–3 cm tumor size are the use of existing equipment, no additional operation costs for tumor removal devices, and the increase in patient's safety.

The ideal locations for the *en bloc* technique are the bladder floor and lateral walls, but not near the ureteral ostium. The development of laser techniques greatly increased the safety of bladder tumor removal at the level of the lateral walls due to the absence of obturator nerve stimulation and predictable small penetration lengths. Waterjet technology has also been introduced into real-life clinically practice. The water in the space of the submucosa layer protects the bladder wall from inadvertent perforations, and facilitates tumor *en bloc* removal. Due to the small sample population in waterjet studies, however, this technique is still under evaluation. Laser technology permits the removal of one-piece bladder tumors located in the anterior wall or in the trigonum. The bladder apex is still the most challenging tumor location, and it is relatively contraindicated for *en bloc* removal due to the high risk of intra-abdominal perforation. Another well-established contraindication for *en bloc* removal is tumors in the bladder diverticula, due to the absence of detrusor muscle in the diverticula wall.

*En bloc* bladder tumor removal appears to be a simple and reliable method that offers many advantages over traditional TURBT:

- It diminishes complications, such as obturator nerve reflex and bleeding.
- It overcomes the incise and scatter problem that conventional resection technique has.
- It preserves the architecture of the tumor and allows optimal staging and grading.
- It seems to reduce the risk of local recurrence due to possibility of negative surgical margin. This may reduce the need for second-look bladder resection.

# Incision: Endoscopic Management of Urethral Stenoses

*Gerald H. Jordan & Kurt A. McCammon*

*Department of Urology, Eastern Virginia Medical School, Norfolk, VA, USA*

## Introduction

Endoscopic management of anterior urethral strictures and posterior urethral stenoses takes many forms. Urethral dilation and incision with cold knife or laser urethrotomy are techniques familiar to all practicing urologists. The use of and indications for urethral stents are sometimes misunderstood. Although these procedures have their role in the treatment of urethral disorders, their use should be predicated upon a thorough understanding of urethral anatomy, etiology of disease, and goals of treatment.

Herein, we review urethral anatomy with special attention to the difference in stricture processes that occur in each segment. The types of available endoscopic techniques are discussed and outcomes in each selected process are reviewed. A stepwise approach to evaluating patients with urethral strictures/stenosis is suggested so that the practitioner can gain an adequate understanding of the disease process prior to initiating treatment.

It is imperative that one understands the differences in urethral processes and expected outcomes based on endoscopic treatment techniques prior to undertaking a course of treatment. Both practitioner and patient should agree upon the expected outcomes of intervention prior to treatment. In only a selected few processes will endoscopic management be expected to be durably successful and because of this, open urethral reconstruction remains the gold standard for many conditions in which the patient's goals are cure of the process.

## Urethral anatomy

An understanding of the urethral anatomy is imperative for the urologist performing endoscopic surgery on the urethra. The anatomic relationships of the urethra and corpus spongiosum must precede discussion of the endoscopic techniques.

The surfaces of the corpus spongiosum is the third erectile body of the penis and lies in the ventral groove between the two corpora cavernosa (Figure 158.1). It is surrounded by the tunica albuginea, which is thinner than the tunica albuginea of the corpora cavernosa. The urethra transverses the length of the penis within the corpus spongiosum and at the distal end, the erectile tissue expands to form the glans penis. The bulbous urethra is eccentrically placed in relation to the corpus spongiosum and is much closer to the dorsum of the penile structures. Distally, the penile urethra is more centrally placed within the corpus spongiosum. The meatus is slit-like in configuration with a vertical axis and is on the ventral aspect of the tip of the glans penis (Figure 158.2).

At the World Health Organization conference in Stockholm the consensus opinion was to subdivide the urethra into six separate distinct areas (Figure 158.3):

- The *Meatus fossa navicularis*, contained within the spongy erectile tissue of the glans penis, terminates at the junction of the urethral epithelium with the skin of the glans. This portion of the urethra is lined with stratified squamous epithelium.
- The *penile or pendulous urethra* lies distal to the investment of the ischiocavernosus musculature but is invested by the corpus spongiosum. This section of the urethra maintains a constant lumen size roughly centered in the corpus spongiosum. It is lined with simple squamous epithelium.
- The *bulbous urethra* is covered by the midline fusion of the ischiocavernosus musculature and is invested by the bulbospongiosus of the corpus spongiosum. It becomes larger and lies closer to the dorsal aspect of the corpus spongiosum, exiting from its dorsal surface

before the posterior attachment of the bulbospongiosus to the perineal body. The bulbous urethra is lined distally with squamous epithelium that gradually changes to the transitional epithelium found in the membranous urethra as it swings upward [1].

- The *membranous urethra* is the portion that traverses the perineal pouch and is surrounded by the external urethral sphincter. This segment of the urethra is unattached to fixed structures and has the distinction of being the only portion of the male urethra that is not invested by another structure. It is lined with a delicate transitional epithelium.
- The *prostatic urethra*, in common use, is the portion of the urethra that lies proximal to the membranous urethra and is mostly surrounded by the prostatic stromal and glandular tissue. Its epithelium is continuous with that of the trigone and bladder.
- The *bladder neck* is the location of the bladder neck musculature, variably surrounded by intravesical protrusion of the prostate. Its epithelium is also contiguous with that of the trigone and bladder.

## Urethral stricture disease

The term urethral stricture refers to anterior urethral disease, a scarring process involving the spongy erectile tissue of the corpus spongiosum also referred to as spongiofibrosis (Figure 158.4). Under the urethral epithelium lies the spongy erectile tissue of the corpus spongiosum and, in some cases, scarring can extend through the tissues of the corpus spongiosum and into adjacent tissues. As the scar contracts, it reduces the diameter of the

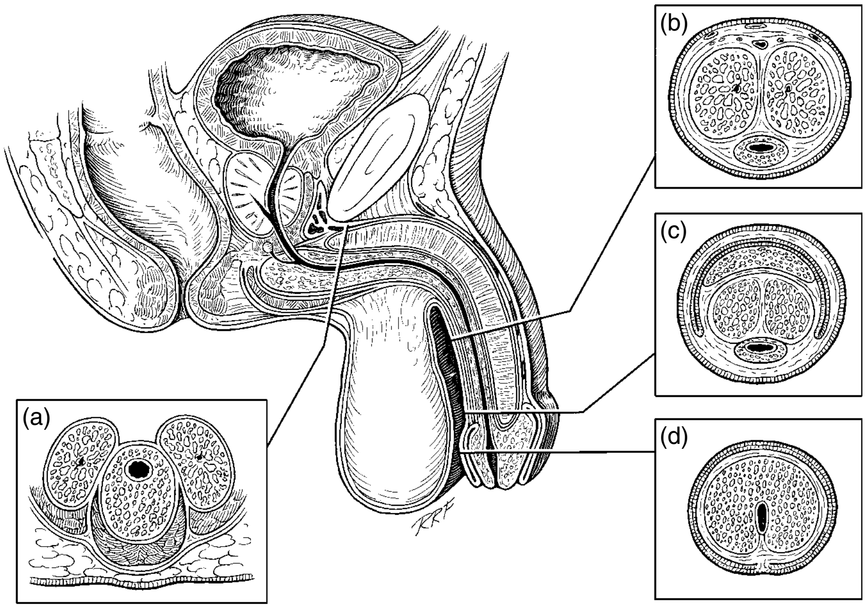

**Figure 158.2** Cross-sections of the anterior urethra. (a) Bulbous urethra. The urethra is eccentrically placed in the corpus spongiosum. Proximally, the corpora cavernosa have split into individual crura, with the urethra lying against the triangular ligament. (b) In the shaft of the penis, the urethra is more centrally placed in relation to the corpus spongiosum, and the corpora cavernosa are intimately fused, separated only by septal fibers. (c) At the coronal margin, the urethra remains relatively centrally placed, and the corpora cavernosa are fused, again separated by septal fibers. The spongy tissue of the corpus spongiosum has become incorporated as the deep tissues of the glans. (d) The fossa navicularis widens somewhat in caliber and is totally surrounded by the spongy erectile tissue of the glans penis. The urethra here is relatively ventrally placed in relation to the body of the corpus spongiosum. *Source:* Carson C, ed. *Topics in Clinical Urology: Complications of Interventional Techniques*. New York: Igaku-Shoin, 1996, pp. 86–94.

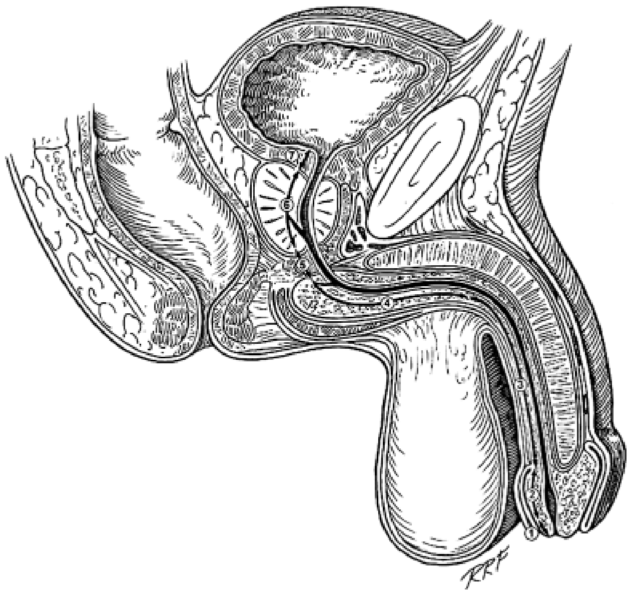

**Figure 158.3** Sagittal section of the pelvis. The urethra is subdivided into the following sections: meatus; fossa navicularis; pendulous or penile urethra; bulbous urethra; membranous urethra; prostatic urethra; and bladder neck. By common usage, the divisions of the meatus, fossa navicularis, pendulous urethra, and bulbous urethra compose the anterior urethra; and the divisions of the membranous urethra, prostatic urethra, and bladder neck compose the posterior urethra. *Source:* Devine CJ and Angermeier, KW. Anatomy of the penis and male perineum. *J Urol* 1994;8(11). Reproduced with permission of Elsevier.

urethral lumen. The normal urethra measures 30 Fr, and its diameter is approximately 10 mm. The calculated luminal area is approximately 78 $mm^2$. If scarring has resulted in a urethra that measures 15 Fr, the lumen is only 55 $mm^2$, or 29% reduced. Scar contraction caused by anterior urethral stricture disease can be markedly asymptomatic early in the process, but as the scarring process and contracture continues and the urethral lumen is further reduced, marked voiding symptoms can develop. This process may occur anywhere within the anterior urethra.

Posterior urethral "strictures" are, in fact, not referred to as strictures at all. By consensus of the World Health Organization conference, the term stricture is limited to the anterior urethra, while distraction defects are those processes of the membranous urethra associated with pelvic fracture and other narrowing of the posterior urethra, urethral contractures, or stenosis [2]. These processes do not involve spongiofibrosis and are thus commonly referred to as stenoses instead of strictures. As with anterior urethral strictures, posterior urethral stenosis is an obliterative process that has resulted in fibrosis and luminal narrowing. This process has usually been initiated by a distraction injury, whether due to trauma or surgical manipulation. Although in some cases these stenoses can be lengthy, the actual process involving the tissues of the urethra is usually well confined. Conditions that result in posterior urethral stenosis include membranous urethral stenosis, prostatic urethral stenosis, bladder neck contracture, vesicourethral distraction, and posterior urethral distraction defects.

## Etiology

Any process that injures the urethral epithelium and/or the underlying corpus spongiosum to the point that healing results in a scar causes a urethral stricture or stenosis. Anterior urethral strictures most commonly result from trauma, infection, inflammatory conditions, or urethral manipulation. In many cases, the inciting event goes unrecognized by the patient until they present with obstructive voiding symptoms.

Traumatic injuries such as straddle injuries are a common example. Penetrating injuries, such as gunshot or stab wounds, may be appropriately treated initially and still lead to development of delayed stricture disease. Iatrogenic trauma is a known etiology of urethral strictures, but with the development of smaller scopes and the recognition of the importance of careful technique, fewer of these cases are now being seen.

The inflammatory dermatosis lichen sclerosus is a commonly seen disease process in patients with anterior urethral strictures. This condition behaves differently from traumatic strictures, recurring quite readily, and thus requires special consideration when contemplating treatment options. Typically, the initial presentation is that of meatal stenosis associated with skin inflammation of the glans penis and prepuce. The inflammation then progresses proximally, perhaps due to distal obstruction, high pressure voiding, and subsequent microextravasation of urine into the corpus spongiosum and glands of Littre.

Infectious strictures associated with gonorrhea, which were commonly seen in the past, are now much less common. With the advent of more effective antibiotics and widely available medical care, gonococcal urethritis today rarely progresses to urethral stricture disease. As we understand the processes currently, nonspecific urethritis due to *Chlamydia* or other organisms does not lead to urethral strictures. The condition of idiopathic urethrorrhagia has in the past been felt to be related to urethral stricture because children were endoscoped for diagnosis. In years past, before the minification of endoscopes, it was felt that those stricture were iatrogenic. However, now there is accumulating evidence that the entity itself can cause proximal bulbous urethral stricture disease [3].

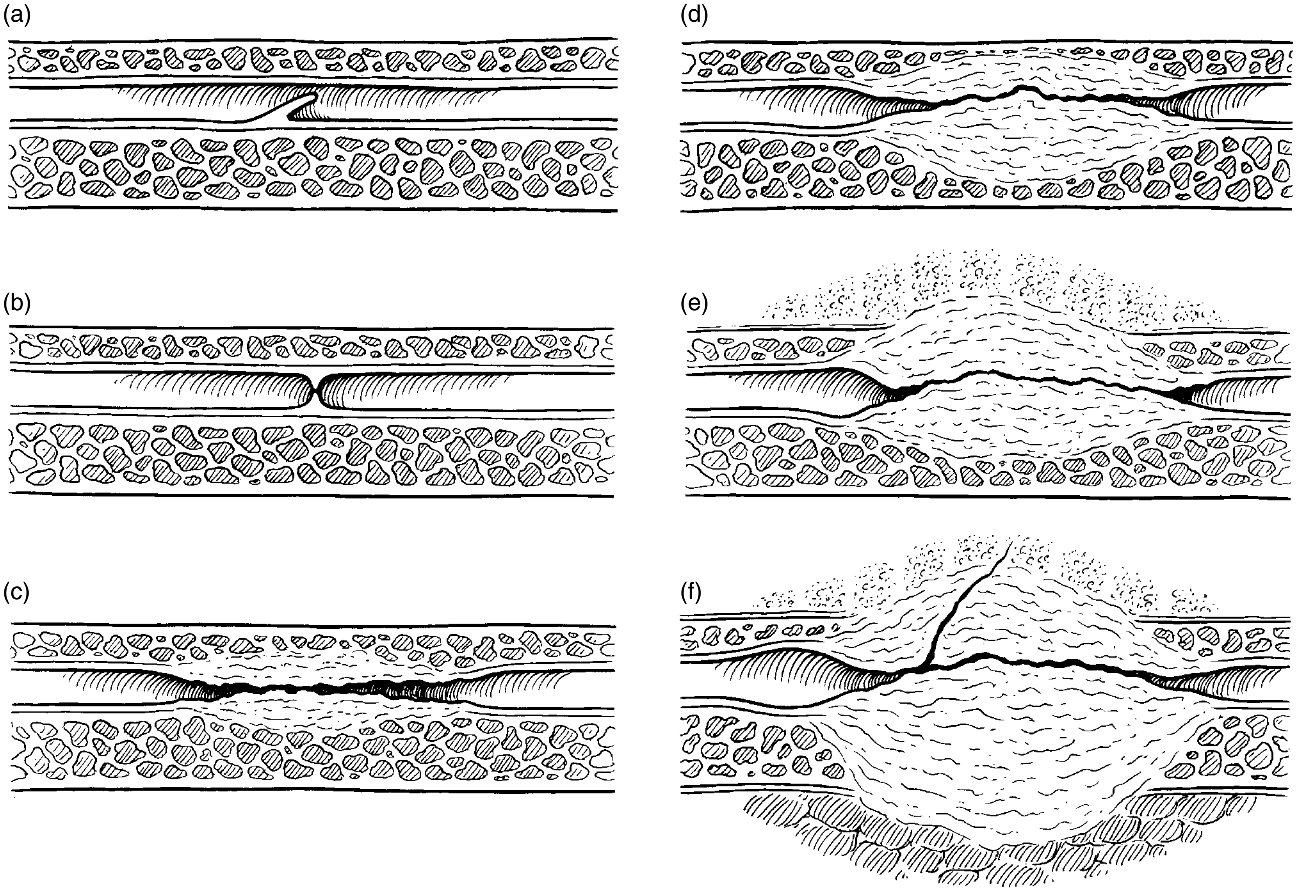

**Figure 158.4** Anatomy of anterior urethral strictures includes, in most cases, underlying spongiofibrosis. (a) Mucosal fold; (b) iris constriction; (c) full-thickness involvement with minimal fibrosis in the spongy tissue; (d) full-thickness spongiofibrosis; (e) inflammation and fibrosis involving tissues outside the corpus spongiosum; (f) complex stricture complicated by a fistula. *Source:* Jordan GH. Management of anterior urethral stricture disease. *Probl Urol* 1987;1:199–225. Reproduced with permission of Wolters Kluwer.

Finally, there are so-called congenital strictures. These strictures occur in infants, are short in length, noninflammatory, and not associated with potential for traumatic etiology. They are the rarest of all strictures.

Posterior urethral stenoses and anterior urethral strictures have many similar causes, although there are also several etiologies specific to the posterior urethra. Membranous strictures may result from urethral manipulation or radiation. Larger French resectoscopes, such as are used for transurethral resection procedures, may cause tearing of the membranous urethra as it departs the corpus spongiosum. Brachytherapy seeds placed distal to the apex of the prostate can lead to radiation damage to this portion of the urethra as well. Prostatic urethral stenosis is rarely encountered, although when seen it may result from iatrogenic endoscopic manipulation of the prostate. Bladder neck stenosis is seen commonly after transurethral resection or radical prostatectomy. It is usually manifest as a short-length stenosis of varying caliber at the junction of the urethra and bladder. In some instances, endoscopic procedures for prostatic enlargement (whether traditional transurethral resection or laser prostatectomy) are performed when there is an unrecognized underlying element of voiding dysfunction. In these cases, the symptoms that prompted treatment will certainly recur. Bladder neck stenosis typically responds well to endoscopic management, by gentle dilation or incision using cold knife, electrocautery, or laser techniques. A more severe form of bladder neck stenosis termed vesicourethral distraction stenosis can be a devastating consequence of radical prostatectomy. It occurs when the vesicourethral anastomosis is disrupted and leads to a longer defect that is quite resistant to endoscopic treatment. Posterior urethral distraction defects are commonly seen with anterior pelvic arch fractures. It has been classically taught that these fractures cause the prostatic apex to separate from the membranous urethra in the manner in which one would remove the stalk from an apple. Newer data, however, shows that these injuries typically occur more distally than the level of the prostatic apex. The level of the distraction defect is usually found just proximal to the departure of the membranous urethra from the corpus spongiosum and thus spares the external urinary sphincter. As in a vesicourethral distraction, this injury leads to extensive fibrosis interposed between the two distracted ends of urethra and is resistant to endoscopic management.

## Diagnosis and evaluation

Patients who have urethral strictures most often present with obstructive voiding symptoms, urinary tract infections, hematuria, dysuria, or urinary retention. Compensatory hypertrophy of the detrusor may initially allow patients to void through a narrowed urethral lumen with few symptoms. In addition, some degree of decreased urethral caliber may not significantly affect the flow dynamics. Patients may not develop significant symptoms until a reduced urethral caliber of 10–12 Fr is reached. Many of these patients will relate an insidious onset of voiding symptoms before progressing to obstructive symptoms or complete obstruction.

First, it is important to question the patient as to history of trauma, especially straddle trauma. A history of urethral infection, previous urethral, prostate or bladder surgeries, and previous catheterizations should be noted. A thorough genital exam should also be performed. Stigmata of hypospadias, lichen sclerosis, previous surgical interventions, and spongiofibrosis may be found. These clues revealed by history and physical exam may give the practitioner additional information as to the etiology of the disease process. This is important to know, as strictures of different etiologies may behave differently when treated.

Prior to any invasive manipulation or investigation, the presence of microorganisms in the urine should be assessed if possible. When the patient is in retention, this may not be feasible and broad-spectrum antibiotic coverage should be given prior to attempt at catheterization, endoscopy, or retrograde urethrography. Urine should be sent for culture when obtained. If it is a nonemergent situation, care should be taken to sterilize the urine prior to proceeding with investigation. In cases of colonization, such as exists in patients with chronic indwelling suprapubic cystostomy catheters, prophylactic doses of culture-specific antibiotics should be given. This is done not with the intent to eradicate colonization, but rather to prevent septicemia during the manipulation.

Passing a urethral catheter is commonly attempted when a patient cannot void. If the catheter does not pass, the nature of the obstruction is determined by dynamic retrograde urethrography. Many cases are managed with acute dilation, but this may not be in the best interest of the patient. When there is doubt, the nature of the stricture should be determined. A suprapubic cystostomy catheter can be used to treat the acute retention and give time to plan more appropriate treatment. Blind passage of filiforms or blind dilation is no longer considered acceptable. The anatomy of the stricture must be determined either through advanced imaging or flexible endoscopy, which at the least, allows the stricture to be visualized and a guidewire to be passed under direct vision through the lumen. In this manner, dilation is not done “blindly,” but with the wire to direct the dilators into the true lumen.

In addition to etiology, the location, length, depth, and density of the stricture (spongiofibrosis) or stenosis must be accurately determined in order to develop a workable treatment plan. The length and location of the stricture can be determined with traditional radiography, urethroscopy, and/or ultrasonography. Some feel that the absolute length of spongiofibrosis may not be evident by ultrasound evaluation alone. Contrast-enhanced studies may be further complemented by the addition of ultrasound studies and together are accurate in determining the length of narrow-caliber annularity [4]. Contrast studies of the urethra are best carried out by or under the direct supervision of the surgeon responsible for treatment of the patient. The depth and density of the scar in the spongy tissue are difficult to determine, but are subjectively best evaluated by physical exam, contrast-enhanced studies that show the appearance of the urethra, and elasticity and appearance of the mucosa by endoscopy. Although magnetic resonance imaging and ultrasonography have been used to help characterize the degree of spongiofibrosis and location of the defect, we find these studies rarely influence the treatment plan developed with traditional radiography and endoscopy.

At our center, imaging includes retrograde urethrography as well as voiding cystourethrography. The patient is placed in a steep lateral oblique position as anteroposterior images often miss lesions or misrepresent their length. Even with gentle technique, extravasation during retrograde urethrography is possible in patients in whom the urethra is markedly inflamed. For this reason, contrast studies should be carried out with contrast material that is suitable for intravenous injection and used either directly from the bottle or diluted according to the manufacturer’s guidelines. It should also be understood that during contrast-enhanced urethrography, more than one projection may be necessary to visualize the stricture. Real-time ultrasound evaluation of the urethra after it has been filled with a lubricating jelly or saline has been described by Morey and McAninch [4, 5]. It is a misconception, however, that ultrasonography always directly visualizes the spongiofibrosis. Morey and McAninch believe that ultrasonography of the bulbous urethra possibly more accurately determines the length of the stricture, which is important in considering an anastomotic repair [4, 5].

An initial endoscopic examination with flexible cystoscope may be necessary after the contrast studies to evaluate the urothelium and assess the degree of spongiofibrosis. A rigid pediatric scope is a very useful tool to help traverse an area of narrow-caliber disease without having to dilate it, as dilation may not be ultimately beneficial. Care should be taken to avoid inciting inflammation of a particularly narrow stricture by passage of the pediatric endoscope. This may cause temporary edema and lead to an episode of acute retention. In the patient who cannot void and has a suprapubic tube, combined contrast studies with endoscopy are helpful in defining the stricture anatomy (Figure 158.5). This evaluation allows delineation of the proximal point of the stricture by endoscopy, and the distal point by retrograde urethrography done simultaneously.

In selected patients, where longstanding outlet obstruction is suspected or where the degree of urethral obstruction does not correlate with symptoms, urodynamic studies may be warranted prior to treatment. Compensatory detrusor hypertrophy in cases of longstanding outlet obstruction may lead to myogenic detrusor failure. In this case, the patient may not void despite correction of the obstructive process. Correction may facilitate intermittent catheterization and thus may be appropriate, but this is an outcome that should be clearly understood by the patient prior to treatment. Likewise, when the degree of symptoms is more severe than would be expected from the degree of luminal narrowing, suspicion is raised for bladder dysfunction or concomitant prostatic obstruction. Video urodynamics maybe helpful to elucidate the level of obstruction, especially if

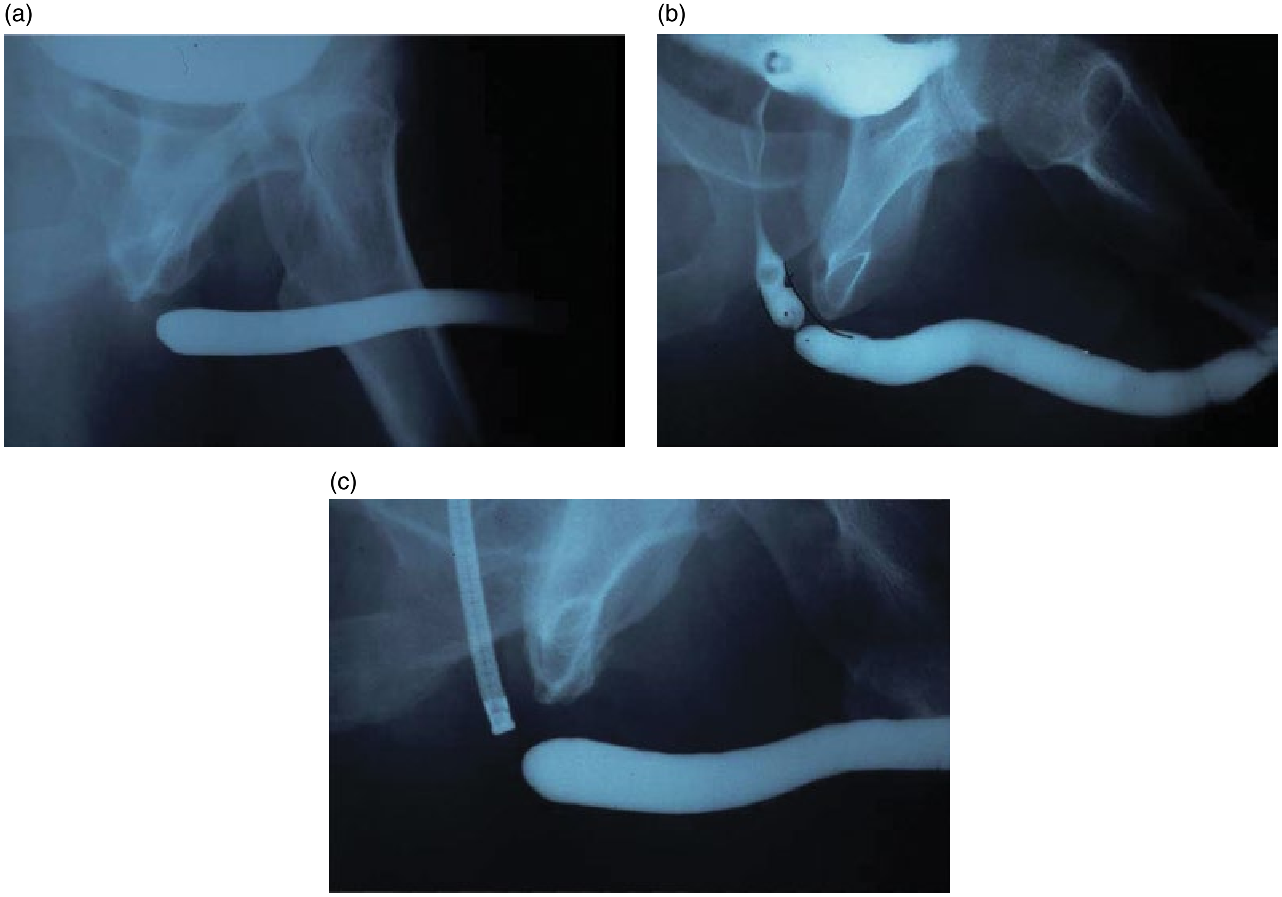

**Figure 158.5** Series of radiographs demonstrating the usefulness of the combination of contrast enhancement with endoscopy. (a) A retrograde urethrogram shows a totally obliterative process involving the proximal bulbous urethra. (b) The patient was successful in relaxing to void; however, there is a suggestion of a wide-caliber annular area proximal to the obliterative process of the bulbous urethra. (c) Endoscopy through the suprapubic cystostomy tube clarifies the anatomy of the proximal urethra and demonstrates the length of the obliterative process. *Source:* Devine CJ and Angermeier, KW. Anatomy of the penis and male perineum. *J Urol* 1994;8(11). Reproduced with permission of Elsevier.

prostatic or bladder neck hypertrophy is present. In these cases, treatment of the urethral narrowing alone may not alleviate obstructive symptoms. In addition, medical treatment of the prostate or bladder neck may decrease or resolve obstructive symptoms without need for treatment of the urethral pathology.

## Treatment

Both the patient and the physician must have a good understanding of the goal of treatment before the treatment choice is made. To this end, treatment options should be discussed with the patient, with care taken to emphasize the anticipated outcome with regard to palliation versus cure. Some patients may prefer palliative stricture management and choose to have periodic dilations in the office, at home, or in the hospital rather than undergo technically detailed open surgery. Others may have cure as a goal and choose open surgical management. The information gained in the evaluation of the stricture is imperative in discussing treatments and expected outcomes with the patient. A thorough knowledge of the etiology of the process is also needed in counseling on risk of recurrence. Many well-described reconstructive procedures utilized today have long-term success rates in excess of 90% and may be used to repair many common types of strictures.

### Dilation

Urethral dilation is the oldest and simplest treatment for urethral stricture disease. It is rarely curative unless the scarring only involves the superficial urethral epithelium. The goal of dilation is to stretch the urethra without tearing it. If bleeding occurs during the dilation, likely the urothelium has been torn rather than stretched and this will produce further scarring.

Filiform dilators have been used for years. The filiform leader is passed initially through the stricture. If the straight tip does not pass, there are spiral tips that may allow passage. The safest way to pass the filiform leader is under direct vision. Also available are a myriad of metal and plastic dilators that may be passed in a similar fashion. Again, blind dilation should be discouraged.

The least traumatic method would be soft dilation techniques over multiple treatment sessions. We believe the safest method currently available is the use of urethral balloon dilation. These catheters may be attached to a filiform tip or passed over a guidewire with an integral coudé tip. For the patient's initial dilation we prefer cystoscopy under anesthesia to allow for placement of a wire which facilitates safe passage of the balloon. In this setting the stricture is truly dilated. A home balloon obturation protocol can then be performed by the patient with the goal of maintaining the operative dilation. This minimizes the amount of repetitive trauma to the urethra and allows the healing process to stabilize while being periodically opposed by the home balloon protocol. We prefer to have the patient use a steroid cream as lubricant for the balloon to decrease urethral inflammation. In addition, oral antibiotic therapy may be used as an anti-inflammatory agent. Initially, the patient starts the obturations several times daily, then daily, then weekly and steadily decreases the frequency as the process allows. This protocol allows for treatment of most types of urethral stricture/stenosis, although as previously stated, distraction defects of the posterior urethra are very difficult to manage in this fashion.

Meatal dilation in cases of meatal stenosis secondary to lichen sclerosis has also been proven to be an effective management strategy. It is easy for patients to perform home dilations using a graduated dilator lubricated with steroid cream. The patients must be thoroughly counseled on proper technique and the goals of dilation if this is to be successful. Frequent nonaggressive episodes of dilation are favored over periodic forceful episodes. In addition to limiting trauma, the patients will usually find dilation to be more comfortable, as very little pain and no bleeding should be encountered. By limiting the amount of distal obstruction, proximal dilation and extravasation should also be minimized, thus decreasing proximal inflammation and possibly stricture formation. With initial persistence and patience, many patients find that eventually the meatal process stabilizes and only infrequent interventions are needed.

Dilation has been shown to be equal to direct-vision internal urethrotomy (DVIU). Steenkamp et al. performed a randomized prospective trial comparing DVIU to filiform dilation in 210 men with urethral strictures [6]. Their results show a 16% greater recurrence rate at 36 months in the dilation group compared to the DVIU group and a 10% higher recurrence rate at 48 months. Stormont et al., in a retrospective review of 199 nonrandomized patients with short bulbar strictures treated with dilation or DVIU, showed that the success rates were equal [7]. At 3 years success rates for the dilation group was 65% compared to 68% for the DVIU group. Because this was a nonrandomized retrospective review there was some selection bias which cannot be excluded.

Complications associated with urethral dilations include cystitis, epididymitis, hemorrhage, recurrent urethral stricture, and false passage.

### Internal urethrotomy

Internal urethrotomy refers to a procedure that opens the stricture by incising it transurethrally. The procedure involves incising through the scar to healthy tissue to allow the scar to expand the lumen with a goal that it will heal with larger caliber. The process of incision essentially sets off a race between epithelialization and wound contracture. If the incised areas epithelialize (i.e. heal by secondary intent) before the wound contracts then the area will stay open. If not, then the stricture has recurred. As with dilation, the goal is to minimize trauma to the unaffected adjacent tissues.

The technique of a cold knife urethrotomy is relatively simple procedure using a 0 or 12° scope with a 19 or 21 Fr sheath. It is important to use isotonic fluid, usually normal saline, to limit the risk of hyponatremia if there is extravasation and possibly the isotonic fluid effect on the tissues during the procedure may be less injurious. A glidewire or ureteral catheter should first be passed through the stricture into the bladder. Something should always be passed through the area before incision to maintain identification of the true lumen. Many surgeons will make the incision at the 12 o'clock position, although we question this because of the location of the urethra within the corpus spongiosum (see Figure 158.2). On cross-section of the corpus spongiosum the thinnest portion is the anterior aspect between 10 o'clock and 2 o'clock. Therefore a deep incision could penetrate through the corpus spongiosum into the intracrural space or corpus spongiosum if the incision is further distal. These incisions into the corpora cavernosa have been associated with erectile dysfunction, likely due to veno-occlusive dysfunction. If it is felt that the spongiofibrosis is deep, an internal urethrotomy will not be curative. We prefer using multiple small radial incisions at 10, 2, and 6 o'clock without cutting too deep into the corpus spongiosum.

Cure rates following DVIU initially were felt to be 80% or above and at first this caused an increase in the use of internal urethrotomy. In addition, many practitioners were more familiar with this type of management than with open urethral reconstruction. The idea of a "reconstructive ladder" was thus popularized. Many felt that it was appropriate to perform multiple endoscopic procedures on recurrent strictures in lieu of opting for open reconstruction. This has since been proven to be faulty logic. Subsequent studies have borne out the issues of endoscopic success and the effect of multiple endoscopic treatments on open reconstruction. Success rates following DVIU have been shown to vary between 35% and 90%. This variation may be dependent on length of stricture, previous treatments, and length of follow-up assessed.

The nature of the strictures being treated with internal urethrotomy has been poorly reported and with various endpoint parameters. This makes comparative assessment difficult because the literature is not clear as to the goal of internal urethrotomy. For many, internal urethrotomy is considered successful if it offers temporary relief. Santucci and McAninch reported curative success rates to be approximately 20% using actuarial techniques [8]. Pansadoro and Emiliozzi as well as others have showed that DVIU is curative in 30–35% [9]. Their study did not show any long-term success for strictures outside of the bulbar urethra. Data show that strictures in the bulbar urethra that are less than 1.5 cm in length not associated with dense, deep spongiofibrosis can be managed with internal urethrotomy with 74% success rates. It has been shown in multiple studies that success of urethral reconstruction is diminished by multiple prior urethral dilations or internal urethrotomies [10–12] (L. Boccon-Gibod, 2005, personal communication). Some have shown a single internal urethrotomy prior to an open urethral reconstruction to be cost effective [13]. Others have refuted this finding and found urethrotomy to lengthen the stricture and make subsequent reconstruction more difficult [14]. In any event, a single attempt at urethrotomy is probably warranted if all of the available criteria favor the chance of success. Otherwise, it may not be cost-effective or of any benefit to the patient if these criteria are not met.

Recurrence of the stricture is the most common complication associated with internal urethrotomy. Complication rates following internal urethrotomy range from 8% to 27%. Complications associated with internal urethrotomy include dysuria, urinary tract infection, septicemia, minor bleeding, retention, scrotal abscess, extravasation, urinary sepsis, and epididymo-orchitis. Erectile dysfunction has also been reported as a complication after internal urethrotomy in up to 11% of patients. Possible causes could be fibrosis after extravasation with infection or injury to the cavernous nerves with deep incision. Other more uncommon complications include urethral–internal pudendal artery fistula leading to high-flow priapism, severe hemorrhage, and urosepticemia. These complications are unusual and are usually associated with aggressive internal urethrotomy.

Since the success rate with internal urethrotomy is so poor, several techniques have been employed to oppose the wound contraction. One option is to leave an indwelling Foley catheter for six weeks after urethrotomy, hoping the urethra will mold around the catheter as it heals. Studies have shown that the failure rates with this technique are equal to those leaving a catheter for 3–7 days. Another option used to oppose the wound contraction forces is home self-catheterization. The catheter is left in place for 3–7 days and once removed the patient is started on a urethral catheterization program. This usually requires more catheterizations in the first 3–6 months but then tapering thereafter. It is our experience that once the patient stops the self-catheterization the stricture recurs, but this technique can effectively manage motivated patients. However, as already discussed, protocols using catheters or balloon obturation can successfully manage patients.

Other techniques used to decrease recurrent stricture formation at the time of DVIU include the injection of steroids or mitomycin C (MMC) at the time of DVIU. MMC has been proposed because of its ability to mitigate scar formation via inhibition of fibroblast proliferation. MMC is injected 0.4 mg/ml in 0.2–0.4 ml for a total of 5–10 ml. This was initially described by Vanni et al. for bladder neck contractures but has been also used recently in urethral strictures with promising results, although longer follow-up is needed [15]. There have been significant complications associated with the use of MMC in bladder neck contractions and therefore its use in urethral strictures need to be monitored closely. Injection of steroids into the stricture may prevent scar formation by enhancing endogenous collagenase and reducing recurrent stricture formation. Mazdak et al., in a randomized control trial using DVIU and 40 mg triamcinolone versus DVIU alone, showed a decrease in recurrence from 50% in the control group to 21% in the treatment group [16]. Standardization of the use of MMC and steroids has not been done so comparisons at this time are difficult.

It has been shown that the length of follow-up as well as length and location of the stricture are of utmost importance in determining success. Boccon-Gibod and Le Portz had a 56% cure rate at 6 months, 43% at 12 months, but only 25% at 2 years [17]. Albers et al. confirmed the lower success rates over time with 95% at 6 months cured, but with longer follow-up at 38 months the success rates dropped to 55% [11]. With a repeat urethrotomy the success rates appear to decrease. One study showed a success rate of 75% with the initial treatment but only 45% success for a secondary treatment. Length of stricture also has a significant effect on recurrence. Steenkamp et al. showed success rates for strictures greater than 4 cm to be less than 20% compared to a success rate of 40% for strictures less than 2 cm at 12 months [6]. Finally a number of studies have shown higher success rates with strictures in the bulbar urethra compared to the penile urethra.

Dilations and/or urethrotomies may be used as part of a palliative strategy almost anywhere in the urethra. With some persistence on the part of a motivated patient and a favorable stricture etiology, some strictures may only need periodic maintenance. Conditions such as lichen sclerosis that have a high propensity for recurrence are often treated in this fashion as few if any "curative" options have been discovered. If either of these methods, however, are being used with a notion of curative intent, the characteristics of the process must be carefully evaluated. The highest reported success rate is in short (<1.5 cm) mucosal strictures of the proximal bulbous urethra as mentioned above. Attempts to manage more distal anterior urethral strictures or stenoses of the posterior urethra will likely have no durable result. In addition, if a single attempt at dilation or urethrotomy fails, subsequent attempts should also be expected to fail. Particularly dismal are the results after dilation or incision of a vesicourethral distraction defect or posterior urethral distraction defect. Incision of a bladder neck stenosis after transurethral resection or radical prostatectomy may be the only exception to the rule of posterior urethral stenoses; these do respond nicely to endoscopic management.

## Lasers

The ideal laser for use in the treatment of urethral strictures is one that totally vaporizes the scar, exhibits negligible peripheral tissue destruction, is not absorbed by water, and is easily propagated along the fiber. As with previously described treatment modalities, care should be taken to minimize injury to adjacent tissues as this may worsen the disease process. There are several types of lasers used for the treatment of urethral stricture disease, including carbon dioxide, argon, potassium titanyl phosphate (KTP), Nd:YAG, holmium:YAG, and excimer lasers. Although carbon dioxide laser appears to be ideally suited, it must be used with a gas cystoscope, which carried the potential risk of carbon dioxide embolus.

For both the argon and Nd:YAG lasers the mode of action is thermal necrosis, which has significant potential for peripheral tissue injury rather than vaporization. The Nd:YAG laser is also used with a bare fiber in contact mode, which carries a risk of forward scatter. Used in the contact mode the YAG energy is transferred to a sapphire tip which will obliterate the scar by vaporization of the tissue. There are no data showing improved results when comparing obliteration to DVIU.

A KTP laser is essentially a Nd:YAG laser that has passed through a KTP crystal, resulting in a reduced depth of penetration. The internal urethrotomy accomplished with the KTP laser is done by passing the fiber over the scar tissue. The holmium:YAG laser has properties similar to the KTP laser and provides both direct cutting and vaporization with minimal scatter. Numerous studies have shown safety with the use of holmium:YAG laser in the treatment of urethral strictures, but success rates appear to be comparable to those for DVIU.

The excimer laser is a vaporizing laser with little forward scatter or peripheral tissue necrosis. Little experience with this laser has been reported but its characteristics warrant further investigation.

The results of laser urethrotomy are mixed but with the advent of new lasers future data may show improved results. A laser with perfect characteristics for treating urethral stricture disease does not seem to exist at this time. Currently, no data exist to show superiority of laser urethrotomy over other techniques. Its indication for usage is similar to that of dilation or cold knife urethrotomy, as previously discussed. Short bulbous strictures, prostatic urethral stenoses, and bladder neck stenoses are the most likely to respond to laser urethrotomy. Little to no durable results should be expected from utilizing laser urethrotomy in more distal anterior urethral strictures, vesicourethral distraction defects, or posterior urethral distraction defects.

### Urethral stents

As discussed previously, when wounds heal, the healing process may turn into contraction. Urethral stents (removable or permanent) are another modality used in opposing the forces of wound contraction after internal urethrotomy or dilation, allowing re-epithelization prior to recurrent stricture formation.

The UroLume® stent (American Medical Systems, Minnetonka, MN, USA) is a permanent, biocompatible, nonmagnetic superalloy woven into a tubular mesh which is self-expanding to 42 Fr. After being deployed it is incorporated into the wall of the urethra and the corpus spongiosum. The UroLume stent is for patients with short bulbar strictures less than 3 cm in length and at least 1 cm from the external sphincter. Available data show that the stent is best employed for short strictures associated with minimal spongiofibrosis. Initial results with the UroLume stent were encouraging, with retreatment rates decreasing from 75.3% to 14.3% after insertion in 105 patients who were followed for 1 year [18]. With longer follow-up, the findings of the North American Study Group show of the 179 patients originally enrolled, 24 patients completed 11 year follow-up. The overall success rate for all patients enrolled at 11 years was less than 30% [19]. This was confirmed in a study with 10-year follow-up from the Netherlands which reported that only 2 of the 15 patients implanted were satisfied [20]. Complications rates with this stent were high and included recurrent stricture, migration of the stent, dysuria, hyperplastic tissue growth, migration of the stent, recurrent urinary tract infections, dysuria, calculus formation and hematuria. The UroLume was removed from the market and is currently not available for implant.

The concept of a temporary rather than permanent stent is appealing. The idea is to leave the stent in place long enough to act as a mold until the wound stabilizes, preventing scar contraction during the healing process. The Memokath urethral stent (PNN Medical, Kvistgaard, Denmark) is made of nitinol and is currently available in Europe, but not in the United States (it is currently under investigation). The Memokath is a thermo-expandable stent, Once it has been placed in position, prewarmed saline is flushed through the stent and urethra, expanding the stent and the bell-shaped ends, which secures the stent in place. The main body of the stent is 24 Fr, with the bells expanding to 44 Fr. The tight spiral structure of the stent prevents urothelial ingrowth.

A large multicenter study evaluated Memokath stents compared to no stent after urethral dilation or urethrotomy in patients with recurrent stricture [21]. The authors concluded that after internal urethrotomy or dilation the stent significantly prolonged time to retreatment compared to the control group. In another study 22 consecutive patients with a recurrent bulbar stricture, mean length 2.4 (1–4.5) cm, underwent DVIU or dilation and subsequent placement of a Memokath stent [22]. All patients underwent stent removal three months after and were then followed clinically with a cystoscopy at 12 months. In this study 17/22 (78%) of the patients remained stricture-free with a median follow-up at 23 months. Those that recurred usually did early and this was thought by the authors to be secondary to spongiofibrosis. Another stent under investigation is the Allium™ bulbar urethral stent (BUS), which is a fully covered, self-expandable, large-caliber metal stent designed for treatment of bulbar urethral strictures. Early studies look promising but more data are needed [23].

## Conclusion

Initial evaluation of a patient with a urethral stricture/stenosis should include a thorough history and physical exam. Length of duration of symptoms, history of trauma, infection, or surgery should be noted. The genitalia should be inspected for scars, inflammatory changes, stigmata of previous treatment, and the entire course of the corpus spongiosum should be palpated and assessed for fibrosis. Thorough radiographic and endoscopic evaluation should also be performed. After the length, location, depth, density, and proposed etiology of the process is known, the patient should be counseled as to palliative versus curative intent of any intervention. In cases of acute urinary retention, thought should be given to placement of a suprapubic cystostomy catheter in lieu of dilation in selected patients.

Only in very carefully selected processes should endoscopic attempts at management be considered to have a reasonable chance at cure. Although both dilation and DVIU have similar rates of success, these rates are only favorable in short, superficial, noninflammatory, proximal bulbous strictures. Any other attempts should be considered palliative. Multiple attempts should not be made in patients who are considered candidates for an open reconstructive procedure. Certain types of strictures, such as those of the meatus and fossa navicularis, may respond well to interval dilation. Other processes, such as posterior urethral or vesicourethral distraction injuries typically do not. That being said, endoscopic management may be very reasonable for a variety of patients and is appropriate as long as the goals are clearly stated and understood.

Currently, there is no laser or urethral stent available that has been shown to drastically revolutionize endoscopic management of urethral stricture/stenosis with or without injection of MMC or steroids. Further study is needed to identify and replicate the characteristics of these tools so that they provide ideal minimally invasive management of this often difficult disease process. For many patients who desire a curative procedure, open surgical reconstruction remains the gold standard at this time.

## Introduction

Bladder neck contracture (BNC) is a well-recognized phenomenon following radical prostatectomy. Also referred to as a vesicourethral anastomotic stricture, this is a different entity from strictures following nonextirpative prostate surgery (e.g. transurethral resection) [1]. Both the definition and the reported incidence of BNC vary within the literature, but recent reports suggest that such fibrosis is becoming less common in the era of robot-assisted radical prostatectomy (RARP). Most providers recognize problematic stenosis as that which precludes passage of a 16 Fr flexible cystoscope. Previously reported rates were as high as 30%, but this has decreased to less than 5% across most modern series [2–5]. Fortunately, many clinically diagnosed cases can be managed effectively with endoscopic intervention. However, recalcitrant contractures may require chronic dilations or patient self-calibration, aggressive open reconstruction, or formal urinary diversion. Some patients may even adopt chronic indwelling catheters to avoid repetitive procedures and the need for pad use or anti-incontinence surgery.

## Etiology

Fibrosis stems from a pathological accumulation of extracellular matrix as part of a wound-healing response. Ideally, healing of the vesicourethral anastomosis would involve optimal blood flow and the absence of excess inflammation. Numerous technical and patient-related factors have been implicated as risk factors for the development of BNC. Urinary extravasation, operative time and blood loss, radiotherapy, surgeon experience, prior outlet procedures, tobacco usage, age, and body mass index (BMI) have all been suggested [6]. Comorbidities such as hypertension, diabetes, and heart disease also seem to increase risk of BNC [7]. Although duration of postoperative catheterization does not appear to be associated with BNC development, early urinary retention after radical prostatectomy increases the risk by nearly fivefold [8]. It seems possible that some cases of obliteration may be due to intrinsic fibrosis (e.g. related to ischemia), whereas others may be from extrinsic fibrosis (e.g. external compression spurred by urinary extravasation).

In 2013, Mucciardi et al. reported on an association between preoperative detrusor underactivity and formation of subsequent BNC [9]. Based on their design, 100 men underwent urodynamic testing prior to radical prostatectomy, with underactivity seen in 60%. This was determined via bladder contractility index ($5Q_{\max} + P_{\det}Q_{\max}$), power at maximum flow, and maximum velocity of detrusor contraction. Following radical prostatectomy, 12 men developed BNC, all of whom had detrusor underactivity, with significant correlation to the severity of dysfunction. The functional state of the bladder may be a surrogate for the overall integrity of the tissue, which may reflect the potential for optimal wound healing.

The ideal surgical technique to prevent BNC is not firmly established. Traditional surgical principles in mucosal anastomoses involve eversion of mucosa with direct apposition, and a well-vascularized and watertight approximation. Failure to properly appose mucosa has been shown to increase the rate of contracture [10]. However, this dogma was brought into question based on reports of improved outcomes with minimally invasive surgery which, unlike open radical prostatectomy, commonly involves a running anastomosis.

Multiple groups have since incorporated a running suture without mucosal eversion during open radical prostatectomy, and have reported an absence of subsequent BNC [11, 12],

As with any anastomosis, visualization is critical. The superior optics afforded by robotic surgery may partially explain the falling rate of BNC, as open radical prostatectomy has become much less common. A multi-institutional study noted a BNC rate of 4.7% following open radical prostatectomy, versus a 0% rate after RARP [5]. Based on multivariate analysis, the only predictive factor was increased length of time before drain removal. This was felt to be a surrogate marker for urinary extravasation. Other authors have suggested that extravasation does not increase the rate of BNC as long as the urethral catheter is maintained until resolution [10]. Laparoscopic and RARP may allow for BNC development via an alternative mechanism. In 20% of BNC after a series of RARP, a foreign body had migrated into the anastomosis [3]. Multiple reports describe this phenomenon as related to Hem-o-lok clips [13–16] (Figure 159.1).

The issue of bladder neck caliber has been debated over time. Previously, it had been thought that sparing of the bladder neck would lead to preservation of continence based on the internal sphincter. However, doing so actually seems to predispose patients to development of BNC based on a small prospective trial [17]. Multiple series have shown that a nonsparing approach with tailoring of the bladder neck to approximately 24 Fr results in lowering the incidence of BNC [18, 19]. Adoption of a nonsparing approach may also alleviate concerns about unnecessarily increasing the risk for a positive surgical margin. However, the potential benefit from increased surgeon experience over time cannot be dismissed. Thus, when surgeons attempt to attribute improvement in outcomes to changes in technique over time, this is confounded by the fact that their experience increases with each additional case.

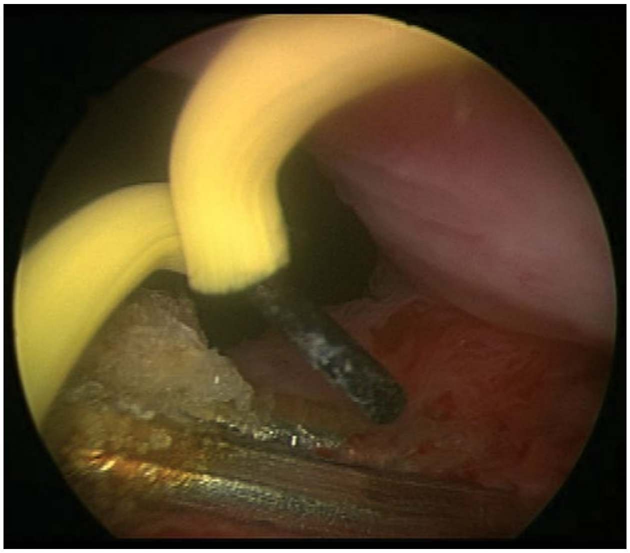

**Figure 159.1** Metal clip at bladder neck.

The impact from radiotherapy seems to vary based on whether it comes before or after surgery. Radiation is felt to result in obliterative endarteritis that predisposes to fibrosis and even tissue necrosis. When administered after radical prostatectomy, the rate of BNC is relatively low (2.6%), without a significant difference between adjuvant versus salvage cases [20]. Salvage radical prostatectomy after radiotherapy, however, results in a higher rate of BNC when compared to open radical prostatectomy in the absence of radiation [21]. BNCs in this setting were also found to be much more difficult to manage [22].

## Evaluation

Patients may be diagnosed with BNC based on obstructive symptoms, urinary retention, or incidentally, based on difficulty with placement of a urethral catheter. Thus, the incidence is likely underestimated. Once patients have been identified, a thorough history should identify all details related to prior surgery, radiation therapy, transurethral instrumentation, and status of urinary continence. It is possible that some patients may owe some of their urinary control to “pathologic continence” consequent to a fibrotic outlet and must be informed that intervention may result in worsening of incontinence [23]. With regard to modifiable risk factors that could impact success of intervention, it is conceivable that tobacco cessation may offer benefit. On multivariate analysis, smoking has been found to be a risk factor for failure of endoscopic management of BNC [24].

Cystoscopy offers formal evaluation of the degree of stenosis. The examining urologist can also acquire a visual impression of the area of the external sphincter and the remainder of the urethra is inspected for any other areas of stricture. It is important to determine, if possible, if the area of obstruction is actually a sphincteric stricture rather than a BNC. Although many cases may be successfully managed at the time of initial cystoscopy with concomitant dilation, others may be recalcitrant and additional data gathering becomes important. If the bladder can be inspected prior to management of a recurrent BNC, one should examine for worrisome changes, such as trabeculation and/or inability to tolerate a reasonable volume of infused irrigation. The location of the ureteral orifices relative to the bladder neck should be noted. Formal urodynamic studies may be useful in some cases, especially if the patient has received radiotherapy. A negative urine culture should be verified prior to procedural intervention.

## Management

### Transurethral dilation

Most BNC will be identified within six months of surgery and can be successfully managed with an initial dilation. This is commonly performed in the office with urethral sounds or filiforms and followers. Blind dilation is ill-advised and may result in false passage and even fistula. Placement of a guidewire via a cystoscope can facilitate the use of a dilating balloon. This applies radial force for controlled dilation and avoids the shearing forces and multiple passes of rigid dilators. Balloons chosen for this purpose may vary between 3 and 6 cm in length, and may increase the lumen to as large as 30 Fr. Controlled inflation under cystoscopic guidance is typically performed up to 14–18 atm for several minutes before deflation and repeat inspection of the bladder neck. Others have described using contrast in the balloon and performing this maneuver via fluoroscopic guidance until the compressive deformity is no longer evident [25]. Success rates with balloon dilation range from 59% to 100% [7, 25–27].

### Transurethral incision

Although commonly employed after failure of an initial office dilation, transurethral incision of bladder neck contracture (TUIBNC) may also be used as a first-line intervention. The typical technique involves 2–4 radial incisions into the fibrosis until the appearance of vascularized tissue or, in some instances, perivesical fat (Figure 159.2). The goal is to enlarge the bladder neck to approximately 24–30 Fr, or to a level where stenosis would be clinically insignificant, and to disrupt the scar in multiple places. Cold knife, electrocautery (Collings knife), or laser can be used to incise the contracture. Once incision has traversed the depth of the fibrosis, bleeding may result and having a modality that also allows hemostasis seems advantageous. Incisions should be directed laterally and the 6 o'clock position should be avoided to prevent inadvertent entry into the rectum. An indwelling urethral Foley catheter (typically 20 Fr or larger) is typically left at the conclusion of the procedure and for 3–7 days.

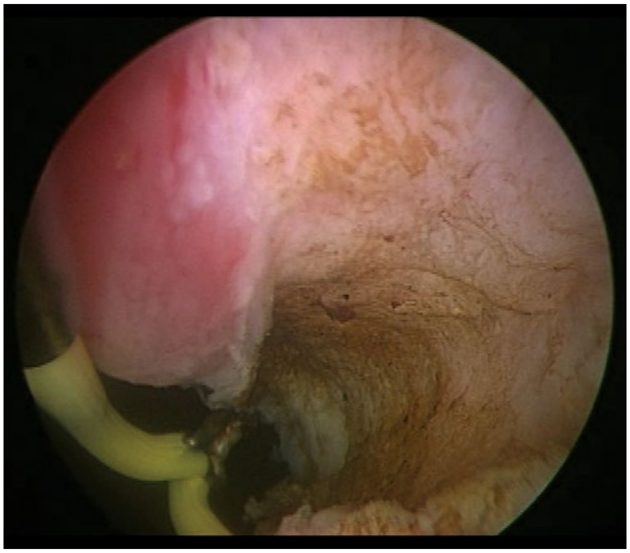

Figure 159.2 Deep lateral incision to perivesical fat.

Review of a 15-year experience with cold-knife TUIBNC for recalcitrant BNC noted a success rate of 73% with either one or two total interventions [22]. Ramirez et al. reported use of a dilating balloon to 24 Fr followed by Collings knife incisions into the fat at 3 and 9 o'clock [28]. Of their 50 patients, 72% achieved success with one procedure, and an additional 14% remained patent with two procedures at a mean follow-up of nearly 13 months.

The holmium laser has also been used in multiple series, and affords the ability to both incise and ablate tissue; it has a defined depth of penetration (0.4 mm). In a comparison between this modality and balloon dilation, TUIBNC, and UroLume stent placement, holmium laser was felt to be most successful in management of BNC, with a success rate of 60% following a single procedure [24]. In a series of 10 patients, Largerveld et al. used a 365 μm fiber at settings of 1 J and 10 Hz (up to 20 Hz if necessary), to incise at 6 o'clock and vaporize from 3 to 9 o'clock [29]. At a mean follow-up of 18 months, there were no recurrences, complications, or worsening of incontinence. Hayashi et al. also found unanimous success in three patients with recurrent BNC using similar technique with follow-up at 11 months [30].

### Intralesional injections

Based on the fibrosis inherent to BNC, multiple attempts have been made to incorporate intralesional injection of agents with potential to augment the wound-healing response after TUIBNC. These have included steroids and antifibrotic agents, most notably mitomycin C (MMC). Following holmium laser incision, Eltahawy et al. injected triamcinolone (40 mg/ml) in 24 patients with recurrent BNC [31]. The majority (83%) had success with one procedure at 24 months, with the remainder only requiring one additional treatment.

In 2011, Vanni et al. reported on outcomes of TUIBNC with concomitant intralesional injection of MMC in 18 patients [32]. Despite having recalcitrant BNC, 72% of patients achieved patency with a single procedures, and another 22% found success with an additional 1–3 procedures. Similarly, Koslov noted patency in all patients treated with this regimen with only 11% of patients requiring a second procedure [33]. In contrast, a combined study of TUIBNC with MMC across eight institutions reported a success rate of only 58% at nine months [34]. In addition, they noted two cases of osteitis pubis and two instances of partial bladder necrosis following subsequent urinary diversion, which led to chronic pain in one patient and rectourethral fistula in the other. At least one group has tried to assert the strength of simple TUIBNC in the absence of intralesional MMC [28]. However, nearly a quarter of the patients in that retrospective single-surgeon study had no prior treatment and many cases were clinically insignificant as they were found incidentally after referral for incontinence. Even with a more favorable population, the outcomes were inferior to those of Vanni et al., and when aggressive TUIBNC was repeated, half the patients failed again. Thus, it seems that further investigation of intralesional adjunctive therapy is worthwhile.

## Intraluminal stenting

Previously, the UroLume Wallstent was used to stent the bladder neck after TUIBNC with initial reports of reasonable success. Unfortunately, there was a high rate of adverse events, including encrustation, tissue ingrowth, infections, hematuria, and pain [35]. Many recipients also developed severe stress urinary incontinence following placement of the device. In 2014, American Medical Systems ceased production of the UroLume, with no alternatives available in the United States. Trials of removable stents (e.g. Memokath SW 28, Allium RPS) in other countries have generated enthusiasm, but future studies are required.

## Endourethroplasty

Although it was originally described for urethral strictures, endoscopic incision and grafting has also been applied to management of BNC [36]. Following TUIBNC, a cystostomy catheter is placed. After 3–5 days, a meshed preputial graft is tubularized around a 22 Fr urethral catheter, which is placed across the bladder neck. The graft is anchored to both the catheter and the perineum with dissolvable suture. Chiou et al. reported success with this approach in two patients at 11 months follow-up [36]. In a similar approach that involved antegrade passage of a fenestrated forearm graft on an endobronchial catheter, Kuyumcuoglu et al. achieved success in 6/11 (54.5%) patients based on cystoscopy at 12 months [37]. Although this is an intriguing concept, given that simple TUIBNC affords similar success the data do not seem robust enough to support this form of management.

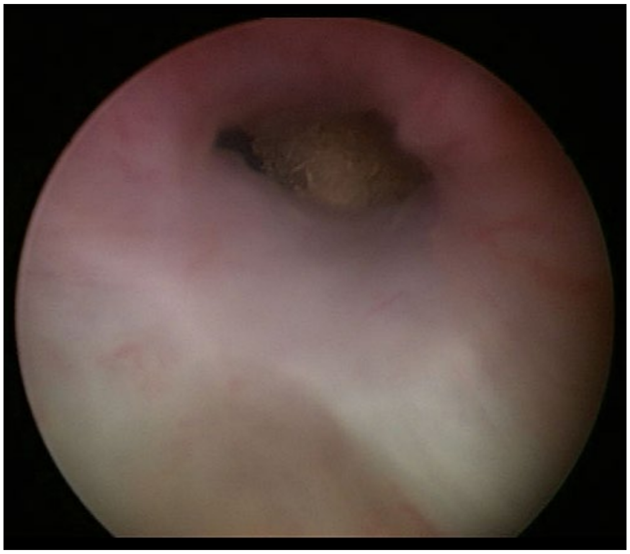

**Figure 159.3** Bladder neck contracture with calculus.

## Surgical reconstruction and urinary diversion

Some patients may not find durable patency despite multiple attempts at endoscopic management. Repeat trips to the operating room can be both frustrating and costly for patients. In addition, failure to definitively correct the BNC may preclude anti-incontinence surgery (e.g. artificial urinary sphincter) for otherwise eligible patients. Although some patients may be offered regimens of self-dilation, data suggest this affords a poor quality of life [38]. Findings on open reconstruction are limited to small series, and this approach has been discouraged by some because of the potential for complications [39]. However, a recently reported single-surgeon series of open reconstruction achieved 92% patency in 12 patients at a median follow-up of 75.5 months [1]. Only 25% of patients were continent postoperatively. In some instances, the degree of tissue devastation and the clinical picture (i.e. small/contracted bladder, dystrophic calcifications of the bladder neck, desire to avoid multiple future procedures to achieve continence, etc.) may prompt consideration of urinary diversion (Figure 159.3).

## Introduction

Stress urinary incontinence (SUI) is the complaint of involuntary leakage of urine with effort, exertion, sneezing, or coughing as defined by the Standardization Sub-Committee of the International Continence Society [1]. SUI affects approximately 25% of women in the United States between the ages of 30 and 60. Surgical therapy has remained the mainstay treatment, although several alternative treatments are available. Anti-incontinence surgical procedures initially emerged in the form of pubovaginal slings, Burch colposuspensions, and bladder neck suspensions, which are still viable treatment options. However, over the last decade, minimally invasive synthetic sling procedures have evolved into the most commonly performed surgical treatment for SUI [2–4].

The era of minimally invasive sling procedures began when Petros and Ulmsten introduced the "integral theory" of female urinary incontinence in 1990 [5]. The theory suggests that a weak pubourethral ligament causes inactivation of the muscle forces which contribute to urethral and bladder neck closure in the regulation of continence. Their subsequent exploration of this topic demonstrated that a damaged or lax ligament is unable to be tightened effectively with sutures, but could be supported at the mid urethra with an artificial neoligament. Thus, Petros and Ulmsten developed the first tension-free polypropylene mesh sling to support the mid urethra. The sling successfully provided continence by reinforcing the pubourethral ligaments with a midurethral tape anchored retropubically [5, 6]. The benefits of this new methodology resulted in acceptable cure rates with decreased morbidity compared with previous pubovaginal slings and Burch colposuspension procedures [6].

Since Petros and Ulmsten's groundbreaking work, synthetic midurethral slings, from retropubic to transobturator, and now single-incision slings (SIS) have steadily evolved. Development of slings has focused on decreasing the unexpected morbidity associated with minimally invasive sling procedures, while striving to retain the 82–95% cure rates seen at 1 year with the "gold standard" Burch procedure [2].

## Midurethral slings

### Retropubic polypropylene tape sling

Petros and Ulmsten developed tension-free vaginal tape (TVT), the first minimally invasive retropubic polypropylene tape (RPT) sling procedure performed under local anesthesia for SUI. The TVT procedure begins with the injection of local anesthetic abdominally and vaginally along bilateral trocar paths. Through a 1.5 cm vaginal incision, bilateral periurethral dissection is performed to the inferior aspect of the pubic symphysis. Trocar needles with attached prolene mesh tape, covered by a plastic sheath, are inserted into the vaginal incision and then passed through the urogenital diaphragm, into the retropubic space just deep to the pubic bone and then out through the suprapubic area. Cystoscopy is routinely performed post procedure to rule out bladder perforations. After the tape is placed at the mid urethra and adjusted with a cough test to ensure continence, the plastic sheath is removed and incisions are closed [5, 6].

Initial 3-year data demonstrated that Petros and Ulmsten's new RPT sling resulted in 86% cure rates and 11% improvement rates [6]. Long-term results observed

*Smith's Textbook of Endourology*, Fourth Edition. Edited by Arthur D. Smith, Glenn M. Preminger, Louis R. Kavoussi, and Gopal H. Badlani.

by Nilsson et al. over an 11.5-year period reported subjective cure rates of 77% and improvement rates of 20% [7]. Randomized controlled trial evidence suggests that TVT has a similar cure rate to colposuspension [8, 9]. Since 1998, several RPT slings have been marketed as either transvaginal or suprapubic needle insertion techniques.

Although the reported efficacy of RPT slings was promising, the blind passage of trocar needles into the retropubic space created a new set of potential complications. A review by Atherton et al. showed that RPT procedures were associated with a 0.2–1% postoperative urinary retention rate, a 3–4% risk of bladder, urethral, or intestinal perforation, and a 1–2.5% risk of major vessel and nerve injury and hematoma in the retropubic space [10]. The incidence of these complications, although infrequent, led surgeons to further explore modifications and improvements in minimally invasive urinary incontinence surgical procedures.

## Transobturator polypropylene tape sling

In an attempt to avoid rare, but unwanted, complications associated with the retropubic trocar needle passage, Delorme developed the "outside-in" transobturator approach to polypropylene sling placement in 2002. By avoiding the retropubic space with trocar passage, the transobturator approach avoids vascular, bowel, and bladder injury while maintaining proper midurethral support [11]. Transobturator tape (TOT) slings involve insertion of trocars around the ishiopubic ramus through the obturator membrane and out through a 1.5 cm midline vaginal incision. After loading the tape onto the trocar, the sling is positioned for midurethral support. In 2004, De Leval reported on a modification of the TOT procedure whereby the trocar was passed "inside-out" from the vaginal incision to the groin incision [12]. Other than the trocar passage technique, this "inside-out" TOT sling is similar to the "outside-in" TOT procedure where the polypropylene tape is positioned at the mid urethra and extends to the obturator space and groin incisions.

Initial TOT sling cure or improvement rates have been shown to be 90% effective, which was comparable to the RPT sling [13–15]. Several other studies have supported the transobturator method and demonstrated TOT slings to be as efficacious as RPT slings [16–22]. Compared to RPT slings, the TOT procedure demonstrates minimal risk of bladder perforation and bowel injury; however, reports of subjective groin pain, possibly related to obturator nerve compression or muscle irritation, have been associated with TOT slings [20]. *De novo* urgency rates also appear to be less after a TOT sling compared to a RPT sling. Botros et al. found decreased *de novo* urgency rate with TOT: 8% for TOT versus 33% for transvaginal RPT and 17% for suprapubic RPT [23].

## Single-incision sling

Soon after the introduction of the TOT slings, engineers began designing the next generation of midurethral slings; the single-incision sling (SIS). Their goal was to mimic the safety and efficacy of traditional RPT and TOT slings, yet lower the complication rate and achieve a better patient experience. The idea was to create a sling that reduced morbidity by avoiding the passage of trocars through the retropubic or transobturator space (and thus limiting injury to major organs), reduced operative time, limited external incisions, minimized anesthesia and postoperative pain, and afforded the possible option of office-based placement.

There have been seven different SISs introduced to the market since 2006. All of the devices are placed via a single vaginal incision and are made of type 1 uncoated polypropylene mesh; however, each SIS device is unique, and they are not interchangeable products. The SISs differ in sling length, trajectory pathway, delivery device, fixation method, and fixation location (Table 160.1). Because of these significant differences, categorizing all SISs as a group is inappropriate and each SIS should be evaluated on its own merits.

The European Association of Urology 2014 guidelines on the treatment of SUI critically analyzed the data on SIS [24]. Level 1b evidence suggests that SISs are just as efficacious as RPT or TOT at 18 months, but that TVT-Secur is less effective than conventional midurethral slings at medium-term follow-up. Although blood loss and postoperative pain are lower for SIS compared to RPT and TOT, other adverse outcomes cannot be fully assessed (Table 160.2). In addition, not all SIS devices have been subjected to randomized controlled trial evaluation and it may be unsafe to assume that they are collectively technically similar devices. Although results to date are promising, further long-term efficacy data on SIS are needed. In addition, appropriate patient selection needs further study, as most SIS studies have been reserved for women without prior anti-incontinence surgery or intrinsic sphincter deficiency.

Contraindications to SIS include: coagulopathy, pregnancy or planned pregnancy, renal insufficiency, immune compromise, and urinary tract infection or obstruction.

On January 4, 2012, the US Food and Drug Administration (FDA) ordered SIS manufacturers to complete postmarket surveillance studies of their products (522 Orders). The FDA's orders came after considering reports of adverse events from manufacturers, physicians, and patients; the September 2011 meeting of the Obstetrics-Gynecology Devices Panel meeting at the FDA; and a critical evaluation of the literature. Manufacturers were not only required to submit study plans to the FDA that address safety and efficacy

| Guideline | Level of evidence/ grade of recommendation |
|---|---|
| Self-fixing single-incision slings are as effective as conventional midurethral slings in improving SUI in women at up to 18 months | 1b |
| Operation times for insertion of single-incision midurethral slings are shorter than for standard retropubic slings | 1b |
| Blood loss and immediate postoperative pain are lower for insertion of single-incision slings compared with conventional midurethral slings | 1b |
| TVT-Secur is less effective than conventional midurethral slings at medium-term follow-up | 1b |
| There is no evidence that other adverse outcomes from surgery are more or less likely with single-incision slings than with conventional midurethral slings | 1b |

Adapted from Lucas et al. [24].

concerns of SIS for SUI, but also to conduct premarket studies comparing SIS to traditional midurethral slings. On June 4, 2012 the first SIS (TVT-Secur™, Ethicon Women's Health & Urology, Somerville, NJ, USA) was voluntarily removed from the market due to concerns over commercial viability in light of changing market dynamics and not over safety or efficacy. Subsequently two other SIS devices (MiniArc™, American Medical Systems Inc., Minnetonka, MN, USA and Ajust™, CR Bard Inc., Murray Hill, NJ, USA) have also been voluntarily withdrawn from the market. The four remaining SIS manufacturers are complying with the FDA 522 Orders and beginning their comparative studies on SIS efficacy and safety.

Over the years, data have emerged regarding the safety and efficacy of each SIS. All of the SIS devices have demonstrated minimal invasiveness with less surgical dissection, shorter procedure time, and less attendant morbidity; however, the long-term results regarding efficacy are now starting to emerge [25–27].

## TVT-Secur system

In 2006, the SIS generation began with the introduction of the Tension-Free Vaginal Tape-Secur™ (Ethicon Women's Health & Urology, Somerville, NJ, USA). TVT-Secur measures 8.0 × 1.1 cm and utilizes the same proprietary macroporous polypropylene fiber used in Ethicon's RPT and TOT slings (Figure 160.1). Besides the shorter length, TVT-Secur's other unique properties include: laser-cut mesh, absorbable fixation tips, and multiple placement approaches. Unlike the tanged mesh edges, laser-cut mesh edges offer the benefits of consistent width and minimal stretch to facilitate proper placement. The innovative 2 cm absorbable fixation tips made of polyglactin 910 (Vicryl) and poly-*p*-dioxanone (PDS) theoretically provided immediate mechanical fixation which, over roughly three months, was replaced by tissue ingrowth. TVT-Secur fixation demonstrated strength over time with initial animal mean pull-out force of 864 g (vs. 771 g for the original TVT) that increased to 6509 g at 12 weeks [28]. The versatile design of the TVT-Secur allowed placement in either the "U" retropubic trajectory position or the "hammock" transobturator trajectory position [25–27] (Figure 160.2). The "U" configuration mimics the RPT placement with the fixation tips placed into the connective tissue of the urogenital diaphragm against the periostium on the pubic bone. The hammock position imitates the TOT trajectory and the absorbable fixation tips anchor into the muscle complex of obturator internus muscle against the posterior edge of the inferior ischiopubic ramus [29]. As the procedure evolved, it became evident that the fixation tips must remain in contact with the respective bony structures in order to maintain stable long-term fixation. Stabilizing the fixation tips to mobile muscular structures alone was found to provide less than satisfactory results [3].

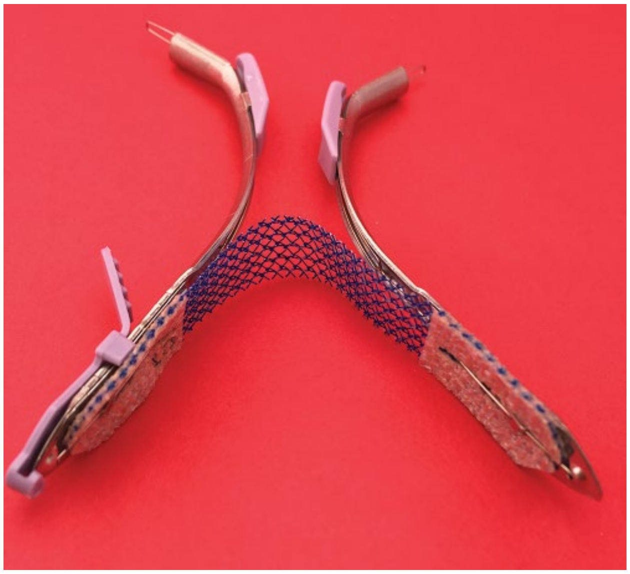

**Figure 160.1** TVT-Secur has laser-cut mesh edges with 2 cm absorbable fixation tips. This mesh measures 8.0 × 1.1 cm.

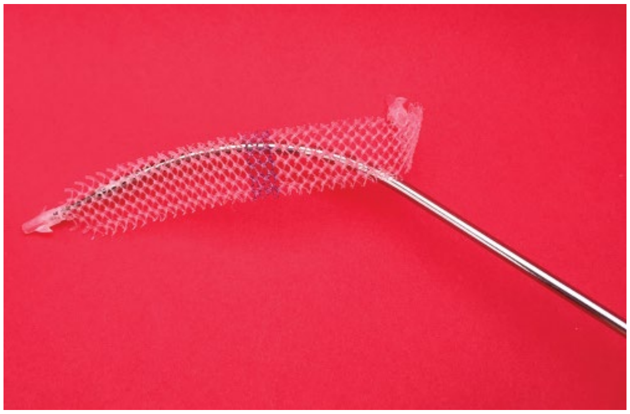

**Figure 160.2** The MiniArc is composed of a macroporous polypropylene mesh measuring 1.1 × 8.5 cm and is fused to self-fixating tips. The 2.3 mm needle and slip-fit mesh-to-needle connection allows easy engagement and disengagement of mesh to needle.

## Procedure

After local infiltration, a 1.5 cm midurethral incision is made in the anterior vaginal wall [29]. The vaginal and paraurethral incision should be made slightly larger than with conventional slings in order to accommodate the TVT-Secur device. To avoid dragging paravaginal tissue during insertion, the paraurethral dissection must maintain its width.

### TVT-Secur "U"

Similar to RPT placement, the dissection is performed to the inferior edge of the pubic bone. The urogenital diaphragm should not be penetrated by the scissors, as this will reduce the holding ability of the fixation tips. Before placing the TVT-Secur, a urethral catheter with guide should be placed to minimize injury to the lower urinary tract by the TVT-Secur inserter. The TVT-Secur is placed flat to and in contact with the back of the pubic bone, while being pushed into the dense connective tissue of the urogenital diaphragm and aimed toward the ipsilateral shoulder. Close contact with the pubic bone assures correct placement. The procedure is repeated on the contralateral side.

### TVT-Secur "hammock"

Similar to TOT placement, the dissection is performed laterally to the lower edge of the ischiopubic ramus. The obturator internus muscle should not be penetrated by the scissors, as this may reduce the holding ability of the fixation tips. The TVT-Secur is placed flat to and in contact with the lower edge of the ischiopubic ramus, while being pushed into the obturator internus muscle. The inserter blade must always stay in contact with the bony surface to achieve long-term fixation. The procedure is repeated on the contralateral side. Proper mesh tension can be achieved with bilateral incremental advancement of the device. Optimal results may not be achieved if the placement is complicated by rotating movements, tearing of the obturator muscle, or placing the device away from the bony pelvis.

### Tensioning

Proper device tensioning is essential to successful placement of the TVT-Secur in the "U" or "hammock" position. Unlike traditional midurethral slings that are pulled into place, the tension of the TVT-Secur SIS will not increase postoperatively. Tensioning options include dynamic cough/Crede stress test or visual assessment, making sure that the sling is flush with the urethra, causing a pillowing effect (filling of the tape pores with suburethral tissue) [29]. Adjustments in tensioning can only be done with the inserters in place and, once the release wires are pulled, it is not possible to reconnect for further adjustments. Cystoscopy may be performed at the physician's discretion and the vaginal incision is closed according to usual method.

## Efficacy

Several of the initial reports of TVT-Secur demonstrated unfavorable outcomes with poor success rates ranging from 67% to 83%, much lower than with the existing traditional RPT and TOT slings [30–32]. Many authors also noted a significant learning curve in the adoption of the TVT-Secur. Improper sling tensioning and lack of immediate mechanical fixation by not placing the fixation tip against the pubic bone or ischiopubic ramus resulted in device dislocation and recurring SUI [30–32]. As experience has evolved, data emerged demonstrating a decline in efficacy of the TVT-Secur in the years following insertion. Several meta-analysis reports demonstrated the TVT-Secur displayed lower efficacy in 1–3 years compared to standard midurethral slings [33–35]. A recent Cochrane review (31 trials, involving 3290 women) comparing SIS operations concluded that the TVT-Secur is inferior to standard midurethral slings for the treatment of SUI. It has been recognized that there was a problem with the fixation method of the TVT-Secur device and other subsequent SIS designs have been modified to eliminate this problem. In March of 2013, Ethicon Inc. decided to voluntarily withdraw the TVT-Secur from the market due to commercial reasons [36].

# MiniArc

One year after the introduction of TVT-Secur, the MiniArc™ (American Medical Systems Inc., Minnetonka, MN, USA) was released in the United States and Europe

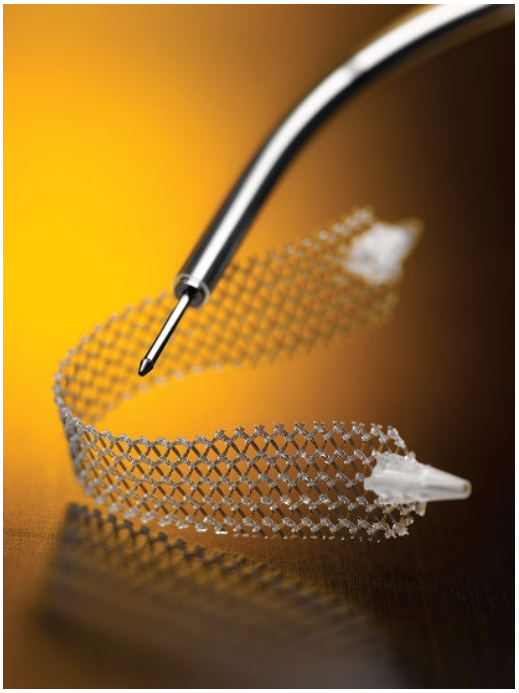

**Figure 160.3** Solyx single-incision sling system. The 9.0 cm polypropylene sling consists of a mesh assembly with carriers fixed to the ends. The delivery device has a handle, needle tip, and midline marker. *Source:* Boston Scientific Corporation, Natick, MA, USA. Reproduced with permission of Boston Scientific Corporation.

as the second SIS on the market. The MiniArc consists of an 8.5 cm × 1.1 cm polypropylene sling with integrated self-fixating tips that anchor into the obturator internus muscle through a single vaginal incision (Figure 160.3). MiniArc's simplified design and approach capitalized on some of the early design criticisms of the TVT-Secur device. Differential design features include the narrow inserter, self-fixation tips, tanged mesh edges, redocking feature, and insertion into the obturator internus muscle. The MiniArc mesh utilizes the same type 1 knitted polypropylene mesh used in American Medical System's RPT and TOT procedures.

The slip-fit mesh-to-needle connection allows easy engagement and disengagement of mesh to needle. Compared to the TVT-Secur, this smooth disengagement feature dramatically lessens the risk of inadvertently moving or loosening the mesh while removing the inserter device. By redocking the needle to the mesh after removal of the inserter, MiniArc's design allows further intraoperative tensioning during placement if desired. With the small 2.3 mm needle diameter, the push-in force required to deliver the MiniArc (2.56 lb) was less than that for the TVT-Secur (4.52 lb) (data on file, American Medical Systems). The polypropylene permanent self-fixation tips were designed to provide short-term holding force that prevents migration during initial tissue ingrowth. Compared to a pelvic floor event at a force of 1.3 lb, cadaver bench testing showed that 5.5 lb of pull-out force is required to remove the MiniArc [37, 38].

Initial skepticism regarding the MiniArc SIS was the initial and long-term fixation strength of the obturator internus muscle and learning the proper tensioning techniques for success.

## Procedure

Similar to other SIS procedures, a 1.5 cm vaginal incision is made at the level of the mid urethra. Bilateral periurethral tissue dissection is performed at a 45° angle toward the vaginal sulcus and the ischiopubic ramus. The sling/needle assembly is guided along the posterior surface of the ischiopubic ramus in a transobturator trajectory toward the obturator internus muscle. Once the integrated sling tip is fixed into the obturator internus muscle, the needle is removed and the procedure repeated on the contralateral side. Upon sling placement, further tensioning of the sling is performed by advancing the needle carrier/sling. The mesh should lie flat against the urethra without any mesh distortion or space between the urethra and sling. Dynamic stress testing (cough stress test and/or the Valsalva test) or visual inspection aids in proper sling tensioning. Cystoscopy may be performed at the physician's discretion and the vaginal incision is closed [39, 40].

## Efficacy

Several promising results have been reported with the MiniArc SIS. Early clinical reports indicate a shortened procedure time (<10 minutes), minimal blood loss, quick learning curve, and ability to perform the procedure under local anesthesia [39–42]. Although the number of long-term studies is limited, those to date support the safety of this minimally invasive procedure with efficacy rates that are similar to those for RPT and TOT.

The first prospective multicenter international trial was published by Kennelly et al., with 157 of the 188 women enrolled available for follow-up at 1 year. Based upon procedural data, the MiniArc was minimally invasive with a quick procedure time (mean 11.0 minutes), minimal estimated blood loss (mean 41.7 ml), short length of hospital stay (mean 9.5 hours), and minimal discomfort post procedure (mean pain score 1.3). At 1-year follow-up, 90.6% of patients had a negative cough stress test and 84.5% had a 1-hour pad weight test of less than 1 g. No complications such as injury to bowel, bladder, urethra, blood vessels, abscess or leg neuropathy occurred in this study. Adverse effects are uncommon and likely due to sling

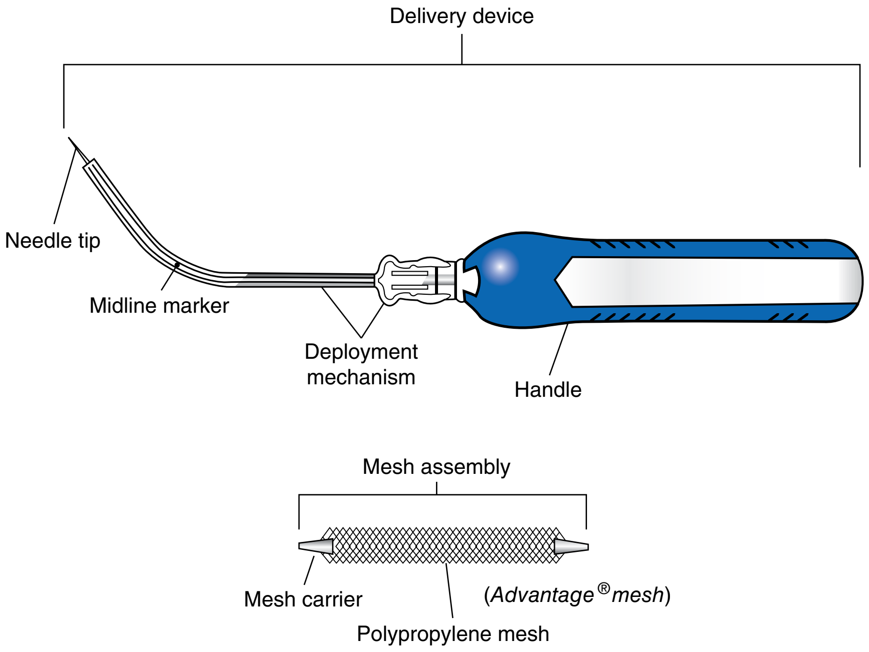

**Figure 160.4** Solyx single-incision sling system. The 4 cm central portion of the mesh is heat sealed and detanged to resist deformation and potentially reduce irritation to the anterior urethral wall. *Source:* Boston Scientific Corporation, Natick, MA, USA. Reproduced with permission of Boston Scientific Corporation.

placement outside the transobturator space or medial groin muscles [27]. However, Gauruder-Burmester and Popken reported that 36.8% of patients developed *de novo* urge incontinence [43]. The placement of self-fixating tips in a tension-free manner is a challenge and depends on factors such as tissue properties, insertion techniques, and tape position/retraction.

Longer term studies have demonstrated the MiniArc's efficacy. Kennelly et al. demonstrated in a 2-year clinical follow-up study that objective improvement/cure rates using the cough stress test and pad weight test were 84.5% and 80.1%, respectively. The subjective efficacy rate in this study was 92.9% [44]. Overall, the MiniArc data regarding efficacy, safety, and patient tolerability is very encouraging. Preliminary reports from the multicenter, prospective 522 postmarket surveillance study comparing 86 patients treated with MiniArc and 86 patients treated with Monarc™ TOT sling as controls were equivalent; however, the final 3-year data have not yet been released. In fact, as of April 2016, the MiniArc is no longer commercially available as the manufacturer ceased market distribution of the device amidst product liability concerns on transvaginal mesh products and because they failed to find a buyer.

## Solyx

The Solyx™ SIS system (Boston Scientific Corporation, Natick, MA, USA) was introduced in North America in 2009. It consists of a delivery device and a 9 cm mesh assembly with nonabsorbable polypropylene carriers on each end (Figure 160.4). These carrier barbs serve to anchor the sling into the obturator internus muscle while permanent tissue ingrowth occurs over time. The mesh assembly is composed of the same polypropylene mesh used in Boston Scientific's RPT and TOT procedures. The 4 cm central portion of the mesh is heat sealed and detanged to resist deformation and potentially reduce irritation to the anterior urethral wall. The delivery device has a snap-fit on the delivery tip, which is designed to prevent premature carrier slip-off during insertion. In addition, this delivery/carrier attachment allows micro-adjustability to loosen and tighten the sling prior to releasing the carrier. The tanged lateral mesh portion may allow for minimal loosening and once the carrier is deposited in the obturator internus muscle, it cannot be reconnected onto the delivery device for additional adjustment [25].

### Procedure

After local infiltration, a 1.5 cm vaginal incision is made at the level of the mid urethra. Bilateral dissection is performed at a 45° angle toward the inferior pubic ramus, creating a pathway for delivery device placement. The mesh assembly is placed onto the delivery device until it is flush with the end and an audible "click" is heard. The delivery device is inserted and advanced toward the obturator foramen just lateral to the inferior pubic ramus and until the midline mark on the mesh is at the mid urethra. The mesh carrier is released into the surrounding obturator internus muscle tissue by holding the deployment mechanism with one hand and pulling the delivery device handle with the other. The delivery device is removed from the incision and the second mesh assembly is placed on the delivery device and contralateral side placement is repeated. Tensioning options include a cough stress test and visual assessment to ensure the sling is positioned against the urethra (allowing a small enough space to place a small instrument or checking that the periurethral tissue "pillows" through the pores in the mesh). With the delivery device still attached to the mesh assembly, modest advances and retreats can be made to tighten or loosen the sling as needed to achieve the desired tension. However, it is important to note that once a carrier is deposited into the tissue, it is not possible to reconnect it for further adjustments [25]. Cystoscopy may be performed at the physician's discretion and the vaginal incision is closed according to the usual method (see Video 160.1).

## Efficacy

There is a paucity of peer-reviewed data on Solyx. In a retrospective review, Serels et al. reported their three-center preliminary results for the Solyx SIS system in patients with urethral hypermobility (Q-tip >30°); 59% of patients had concomitant repairs [25]. At a mean follow-up of 6.5 months (range 5–8 months), 95% (60 of 63) were dry both by subjective patient assessment (patient states they are completely dry) and objective physician assessment (negative standardized cough stress test). Only 2 of 63 patients had transient urinary retention and there were no adverse events of bladder, bowel, vessel or nerve perforations, and no erosions, extrusions, muscle or groin pain. Castellier et al. performed a review on 43 prospective and comparative studies looking at patients who underwent SIS placement. According to their research, the efficacy for Solyx SIS was as high as 95% [45]. These short-term, prospective analyses provide encouraging data that will need to be confirmed in larger, prospective studies with longer follow-up. Currently the multicenter, prospective 522 postmarket surveillance study comparing 140 patients treated with Solyx SIS and 140 patients treated with Obtryx II™ TOT sling as controls is currently on going and no data have been released.

## Needleless

The Needleless® System (Neomedic International, Terrasa, Spain) quietly emerged from Europe in 2007. It consists of a 12 cm × 1.4 cm macroporous monofilament polypropylene mesh with a blue midline suture (Figure 160.5). Unique to this device is the lack of inserter needle or anchor system. The patented lateral pocket positioning system provides the initial holding strength in the obturator internus muscle. With only 16% less surface area for tissue ingrowth than a traditional TOT sling, the Needleless sling hopes to offer the same clinical benefits as a TOT sling through a single vaginal incision [46]. In addition, no sharp introducer needles are required to implant the sling, which enhances patient comfort and is fundamentally attractive for local anesthesia.

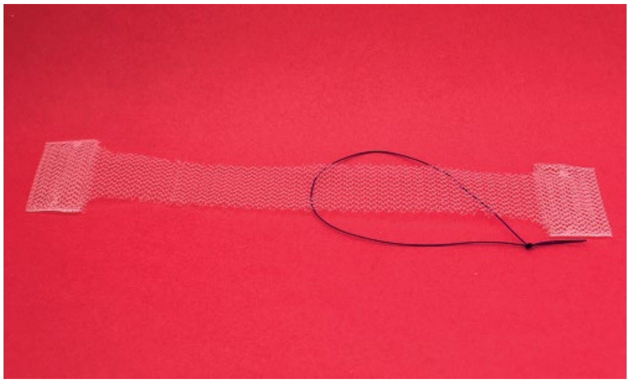

**Figure 160.5** The Needleless sling has a patented lateral pocket positioning system. The midline blue suture can be removed intraoperatively or left in place for a postoperative adjustment.

## Procedure

After local infiltration, a 2 cm incision is made at the mid urethra on the anterior vaginal wall. A horizontal submucosal tunnel is dissected to the edge of the ischiopubic ramus. The Needleless sling is prepared by introducing a surgical forceps (i.e. tonsil) in one of the terminal pockets of the sling. The forceps are inserted into the pocket of the sling, and the pocket is folded between the jaws of the forceps. The folded pockets are introduced through the dissected spaces directed at approximately 30° from the midline. The Needleless mesh pockets should be guided to the 10 o'clock and 2 o'clock positions, respectively, relative to the urethra. The surgical forceps and mesh sling are pushed into the obturator internus muscle to the point that the central sling traction thread is within 1 cm from the urethral midline. Release of the sling is accomplished by opening the forceps, extending the sling pocket positioning/anchoring system, and then carefully closing and removing the forceps. The process is then repeated on the contralateral side. The sling is placed flush with the urethra while countertraction is used on the central thread to aid in centering the sling. Intraoperative adjustments of the sling can be made by reinserting the forceps into the pockets on either side and advancing the sling further into the muscle. Cystoscopy may be performed at the physician's discretion and the vaginal incision is closed according to the usual method. The traction thread should be cut off, although it may be left in place for a maximum of 48 hours, and can be used to loosen the mesh in the case of postoperative urinary retention [46] (see Video 160.2).

### Efficacy

Several promising results have been reported with the Needleless sling since 2007. Navazo et al. reported their preliminary experience with their first 120 patients undergoing the Needleless procedure [46]. All patients had urodynamically confirmed SUI and 83% (100 of 120) had concomitant repairs. The mean procedure time was 10 minutes (range 5–15 minutes). Based upon a negative cough test, 100 patients (84%) were objectively cured, 10 (8%) improved their incontinence, and 10 (8%) were considered failures. This series did not report any cases of inguinal pain, hemorrhage, hematoma, vascular, or visceral damage; however, there was one sling extrusion managed successfully with estrogen cream.

Amat et al. compared the Needleless system with transobturator TVT-O™ sling (Ethicon Women's Health & Urology, Somerville, NJ, USA). A total of 158 women were studied and followed up 1 year after the procedure. This noninferiority test demonstrated that 87.5% of study participants who received the Needleless SIS (63 patients) and 90% of the TVT-O group (54 patients) presented with negative stress test after the study. The satisfaction rate and complication rate were similar across the two groups [47]. Another study published by Martinez Franco and Amat Tardiu compares Needleless SIS and TVT-O over a 3-year period. This was a single center, noninferior, randomized study that looked at 257 patients who received either the TVT-O or the Needleless SIS. One hundred and eleven women in the Needleless group (84.7%) and 54 women in the TVT-O group (88.9%) had negative stress tests. The complication rates were similar between the two groups, but the TVT-O group had statistically more significant postoperative pain [48].

The manufacturer used data from the study by Martinez Franco and Amat Tardiu to fulfill the 522 postmarket surveillance order. This was a prospective study that compared the safety and effectiveness outcomes of 143 patients treated with Needleless SIS and 114 patients treated with TVT-O [48]. At 3 years, the Needleless sling success rates were noninferior to the TVT-O sling, with 86% (112/130) of the Needleless SIS patients having a negative cough stress test as compared to 87.9% (95/108) of the TVT-O group. The most common adverse events reported were *de novo* urge incontinence (ranged from 8.3% to 11.7% in the Needleless sling group through 36 months and from 13.0% to 15.8% in the TVT-O group) and recurrent incontinence (ranged from 13.6% to 15.6% in the Needleless sling group through 36 months and from 5.9% to 12.0% in the TVT-O group) for both groups. There were no reports of mesh erosion in the bladder, other pains, *de novo* dyspareunia, infection, other urinary problems and neuromuscular problems in either group through 36 months [48].

Initial reports of the Needleless procedure are encouraging. Further multicenter studies with longer follow-up need to be published to confirm the long-term effectiveness of this technique.

## Ajust

The Ajust™ Adjustable Single-Incision Sling System (CR Bard Inc., Murray Hill, NJ, USA) was introduced in Europe in 2008 and North America in 2009. It was designed to offer all the benefits of a TOT sling procedure through just one vaginal incision. The Ajust sling system includes: a fully adjustable sling with self-fixating polypropylene anchors; an introducer designed to place the sling in the obturator membrane; and a flexible stylet used to lock the sling after adjustment (Figure 160.6). Unlike other SISs, the Ajust sling is placed through the obturator membrane, mimicking a traditional TOT sling placement. This new sling utilizes the obturator membrane fixation through a single-incision approach versus the three-incision pull-through approach of traditional TOT slings.

For most SIS devices, adjustment is dependent upon manipulating the introducer/needle mechanism and postinsertion adjustment is not feasible. The Ajust polypropylene mesh sling features two anchors, one fixed and one adjustable, and is constructed with a suburethral section, as well as a tubular adjustment mesh that slides in either direction through the anchor. These mesh design features allow bidirectional independent adjustment (tightening and loosening) of the sling mesh relative to the anchors without visual obstruction from the introducer in the surgical field. After optimal sling tension setting, the flexible stylet is utilized to lock the sling into place.

### Procedure

After local infiltration, a 1.5 cm incision is made at the midurethral level on the anterior vaginal wall, and a horizontal tunnel is created up to the edge of the ishiopubic ramus. The device is then inserted horizontally toward

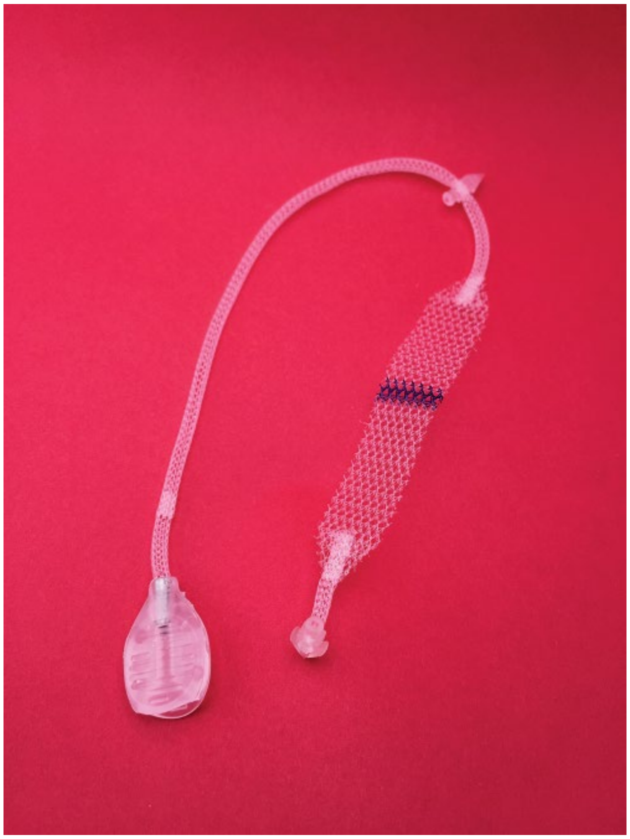

**Figure 160.6** Ajust adjustable single-incision sling. The Ajust polypropylene mesh sling features two anchors, one fixed and one adjustable. Postinsertion adjustments can be made by loosening or tightening the mesh relative to the fixed anchors.

the cephalad margin of the ischiopubic ramus, and pushed straight into the obturator internus muscle. Once the fixed anchor passes the ischiopubic ramus, the surgeon must pause from the original push while pivoting the introducer handle past the midline, and then resume a second straight push maneuver to place the anchor completely through the obturator muscle and membrane. The midline indicator must be deviated past the midline toward the fixed anchor side to confirm proper depth of placement. The fixed anchor is then released and traction is applied to the suburethral portion of the sling to confirm proper anchor engagement. The adjustable anchor is then loaded into the introducer and the steps are repeated on the opposite side. Once the adjustable anchor is correctly placed, the adjustment tab and tubular mesh is then pulled until the surgeon achieves the desired "set-point" of the suburethral sling. Once optimal setting has been achieved, the flexible stylet is used to advance the sling lock into the adjustable anchor, locking it in place.

The system is designed to permit post-anchor insertion bidirectional tension adjustability (loosening and tightening) after the sling implantation without further insertion of the introducer. Cystoscopy may be performed at the physician's discretion and the vaginal incision is closed according to the usual method.

## Efficacy

Several peer-reviewed studies of Ajust SIS demonstrate favorable outcomes with high success rates, short operative times, minimal morbidity, and the ability to perform the procedure under local anesthesia [49–51]. Since then, more peer-reviewed studies have emerged. Natale et al. looked at 95 females in a 2-year prospective, multicenter, randomized control trial. Of the 95 study participants, 92 had completed the 2-year follow-up. Objectively, the cure rate was 83.7% and subjectively, 81.5%. No intraoperative complications were noted. However, postoperatively, 9 patients presented with *de novo* urgency. Other adverse postoperative events also included leg pain, mesh extrusion, and recurrent urinary tract infection. Patients in this study demonstrated a statistically significant improvement in their quality of life (based on the King's Health Questionnaire) [49]. Martan et al. presents a multicenter, prospective randomized study with a 2-year follow-up for 66 study participants (of whom only 63 completed the study). The authors divided the cohort into two groups: the Ajust ($n = 33$) and the MiniArc ($n = 33$). The study found that approximately 83.9% of the Ajust group were cured or improved, based on a Likert scale. Objective cure rates, as evidenced by a negative cough test, was 93.5% in the Ajust group [50]. Xin et al. also studied the Ajust single-incision mini sling versus the more traditional TVT-O. In their reports, the subjective and objective cure rates between the two midurethral slings did not have any statistically significant differences (94.4% vs. 90.7%, $P = 0.171$; 97.2% vs. 90.7%, $P = 0.195$). Postoperatively, the Ajust group had much less pain. Also, the intraoperative blood loss, operative times, and recovery were significantly shorter [51].

Overall, the various reports of the Ajust sling have demonstrated its short-term effectiveness in treating genuine SUI, with limited and mild complications or adverse events. Unfortunately, as of May 2016, the Ajust SIS is no longer commercially available in the United States as the manufacturer ceased market distribution of the device amidst product liability concerns on transvaginal mesh products.

## Ophira

The Ophira™ Mini Sling System (Promedon, Cordoba, Argentina) was introduced in South America in 2008 and received FDA approval in 2012. It consists of a retractable insertion guide and a 0.9 × 10.2 cm mesh assembly made of type 1 polypropylene mesh with thermos-sealed edges and a multipoint fishbone-like polypropylene anchor tip at each end. The anchor tips serve to anchor the sling into the obturator internus muscles on the same plane as the tendinous arc. The Ophira SIS system has blue loosening sutures at the base of the fixation arms which gives the provider the ability to correct tensioning during sling placement.

### Procedure

After local infiltration, a 1.5 cm horizontal incision is made at the midurethral level on the anterior vaginal wall. Bilateral dissection is performed in the direction of the ascending pubic ramus bilaterally. Next, dissection is performed in the direction of the ascending pubic ramus bilaterally. The fixation arm of the sling is fixed to the retractable insertion guide. The guide is inserted in the vaginal incision along the posterior surface of the ishiopubic ramus in a transobturator trajectory and advanced toward the obturator membrane until the central mark on the sling disappears under the ipsilateral side of the incision. The center mark ensures the depth of the sling is correct and the sling is centered. Once the sling is centered, the sliding button mechanism on the insertion guide is activated to release the mini sling. The procedure is repeated on the contralateral side. However, the depth of insertion of the second fixation arm on the contralateral side will be the determining factor of final tension. Dynamic stress testing (cough stress test/Valsalva test) or placement of an instrument (i.e. tonsil) between the urethra and sling to act as a spacer may be performed to obtain correct tension. If excessive tension is noted, the loosening suture on the sling may be pulled to loosen the sling. Once the optimal tension is achieved, the blue loosening suture is removed. Cystoscopy may be performed at the physician's discretion and the vaginal incision is closed according to the usual method.

### Efficacy

Despite being developed in 2008, there are only a few peer-reviewed studies available for the Ophira sling. Smith et al. compared outcomes at 12 months between the Ophira SIS and a TOT sling. This prospective observational study looked at 30 patients who received the Ophira sling and 31 patients who received the Obtryx™ TOT sling. At 12 months, approximately 93.3% (29 patients) with the Ophira slings reported significant improvement in symptoms and 90% (27 patients) had a negative cough stress test. These numbers are very similar to the TOT group in that 29 of those patients (93.5%) reported improved symptoms and 29 patients (93.5%) had a negative cough stress test [52].

From February 2008 until February 2011, Palma et al. conducted a multicenter international clinical trial that followed 178 patients who received the Ophira sling for SUI. A total of 77.5% (138/178) patients completed the 1-year study follow-up. Only 3.9% of patients continued to have a positive stress test. The authors suggest that the successful treatment of SUI in this population was due to the multiple point fixation arms that provide stability over time. In addition, no major complications were noted in this study. Minor complications included: mesh exposure (3 patients), urinary retention (3 patients), urinary tract infection (8 patients), and *de novo* urge incontinence (7 patients) [53].

Regarding the 522 postmarket surveillance study, the manufacturer changed the indications for use and therefore the 522 Order is no longer applied to this device [54]. The initial reports of Ophira efficacy and safety are encouraging.; however, more studies with long-term follow-up are needed to fully evaluate the Ophira sling to prove sustained durability and efficacy.

## Altis

The Altis® SIS (Coloplast Corp., Minneapolis, MN, USA) was introduced in the United Kingdom and received FDA approval in 2012. Similar to the Ajust, this sling was designed to offer all of the benefits of a TOT sling through one vaginal incision. Mimicking a traditional TOT sling placement, the Altis sling is placed through the obturator membrane with the aid of helical introducers and allows postinsertion adjustability. The Altis polypropylene mesh sling features two anchors, one fixed and one adjustable, connected to a 1.1 × 7.75 cm central portion of heat-sealed mesh by polypropylene monofilament suture (Figure 160.7). The dynamic anchor is designed for bidirectional adjustment intraoperatively via the size one polypropylene monofilament suture sonic welded to the sling.

### Procedure

After local infiltration, a 1.5 cm incision is made at the midurethral level on the anterior vaginal wall, and a horizontal tunnel is created up to the edge of the

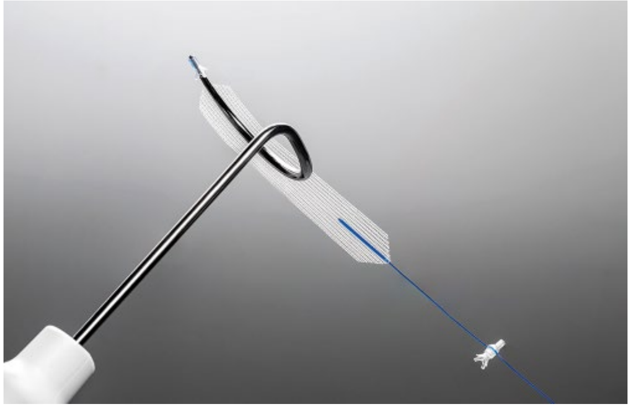

**Figure 160.7** Altis single-incision mini sling. The anchor is placed on the introducer delivery tip. *Source:* Coloplast Corporation, Minneapolis, MN, USA. Reproduced with permission of Coloplast Corporation.

ishiopubic ramus. The static nontensioning anchor of the sling assembly is placed on the appropriate introducer. The introducer/sling assembly is placed into the midline vaginal incision using an inside-out technique. Once the introducer/anchor tip is passed posterior to the ishiopubic ramus, the introducer/anchor tip is turned approximately a quarter turn, which advances the anchor through the obturator membrane. The dynamic anchor is placed on the opposite introducer delivery tip and the same technique of delivery is performed to place the dynamic anchor into the opposite obturator internus muscle. Tensioning of the sling is performed by pulling the monofilament suture loop across the patient's midline until desired support is achieved. If necessary, a blunt instrument may be used to gently pull down the sling to loosen it. Once desired support is achieved, the tensioning suture is cut as close as possible to the pelvic side-wall. Cystoscopy may be performed at the physician's discretion and the vaginal incision is closed according to the usual method (see Video 160.3).

### Efficacy

The Altis SIS was the first SIS to undergo an investigational device exemption (IDE) clinical study collecting safety and effectiveness data required to support their premarket notification 510(k) approval application. A 12-month IDE clinical study was conducted at 17 sites with 113 female subjects with confirmed SUI [55]. At the end of 12 months, 90.1% of patients had a 50% reduction in pad weight and 90.1% had a negative cough stress test. With regard to quality of life, 89.3% and 90.3% of patients had at least a 50% improvement in Urogenital Distress Inventory (UDI-6) and Incontinence Impact Questionnaire (IIQ-7) scores, respectively. In total, 89.3% of patients reported improvement of very much or much better on the Patient Global Impression of Improvement (PGI-I) at 12 months. Three serious adverse events were reported: a pelvic hematoma which drained spontaneously and two of four mesh extrusions which occurred in the study. The IDE study concluded that the Altis SIS system met all endpoints of the study and performed comparably with legally marketed predicted devices. At 12 months, subjective measures reported a cure rate of 84.0% and an objective cure rate of 90.2%. Adverse events included one case of vaginal extrusion, and three cases of vaginal exposure of the adjustment thread which were managed conservatively [56].

Currently the prospective, 522 postmarket, multicenter, cohort assessment comparing Altis SIS ($n = 178$) and transobturator and/or retropubic slings ($n = 178$) in the treatment of SUI at up to 40 US and international sites is ongoing and no data have been released. Longer term outcome studies are not currently unavailable. These longer term studies are needed to fully evaluate the Altis sling. However, initial reports on the safety and efficacy of Altis are encouraging and show it to be competitive with other comparable products that are legally marketed.

## Conclusions

SUI is debilitating and treatable with surgical interventions. Excellent success rates have been reported with both the RPT and TOT slings; however, both approaches require blind passage of trocars that risks visceral and vascular damage. Since 2006, SIS devices have been used in an attempt to decrease the morbidity associated with the minimally invasive approach. However, these procedures must be approached with caution and providers must understand that minimally invasive slings are not simpler, but require much attention and detailed dissection. Due to the significant differences in technical design between SIS devices, it would be misleading to make general statements about them as a class of operations. It is anticipated that decreased complications, high continence rates, and ease of application under local anesthesia may eventually allow SIS placement to become an office procedure. The encouraging initial results from SISs must be demonstrated over the long term, and comparative trials to the current gold standard RPT and TOT slings continue to be needed to solidify SIS device placement as a first-line treatment option for women with SUI.

## Introduction

Recent advances in our understanding of the underlying pathophysiologic mechanisms responsible for stress urinary incontinence (SUI) in women have led to the development of innovative new surgical methods for its treatment. A number of different surgical options are present for patients with SUI, including retropubic suspensions, sling and tape procedures, artificial urinary sphincters, and periurethral bulking agents. Concerns over the morbidity associated with open surgical treatment and the safety of the use of surgical mesh implants has driven investigators to investigate the role of periurethral bulking agents as a minimally invasive alternative treatment. The lower morbidity of the endoscopic approach and ability to be performed in an outpatient setting under local anesthesia are appealing for patients with significant medical comorbidities and is part of the current trend towards less invasive surgical treatments. A recent study of case volumes at the time of certifying examinations for urologists demonstrated that the use of endoscopic injections has remained a stable element of the urologist armamentarium, comprising 15% of all female incontinence procedures [1]. While male SUI is a common problem following surgical treatment such as radical prostatectomy, bulking agents have demonstrated limited efficacy and have fallen out of favor in the treatment of male SUI [2, 3]. As such, this chapter will focus on bioinjectables in the treatment of female SUI. Although the long-term efficacy and durability of these treatments has been questioned, for the appropriately selected patient, bioinjectables can play an important role in the treatment of SUI.

## History

Bulking agents have a long medical history in fields outside of urology. They have been used for gastroesophageal reflux, scars, and wrinkles, as well as for patients with glottic insufficiency [4, 5]. The first use of urethral bulking agents (UBAs) in the treatment of SUI occurred in 1938 when Murless used sodium morrhuate or cod liver oil as a sclerosing agent in the anterior vaginal wall of 20 patients, attempting to create an fibrotic inflammatory response [6]. Others used similar agents, but until 1973 this approach was seldom used due to high complication rates. Berg [7] and Politano et al. [8] popularized the use of polytetrafluoroethylene (Teflon) during the 1970s. Reports of significant complications including particle migration to the lungs limited the utilization of Teflon in periurethral injections [9]. Urethral bulking only became widely popular following the US Food and Drug Administration (FDA) approval of bovine glutaraldehyde crosslinked collagen, marketed as Contigen (Allergan, Dublin, Ireland) in 1993. While Contigen was withdrawn from the market by its manufacturer in 2011, several different bulking agents remain available for use [10].

## Mechanism of action

The mechanism of action of injectable agents results from augmentation of the urethral wall and subsequent increase in urethral resistance. The resulting improvement in urinary incontinence is not associated with a corresponding increase in voiding dysfunction. This is because the “seal” that is formed by restoring mucosal

coaptation does not occlude the urethra. The urethra maintains the ability to funnel and open, with no change in detrusor pressure to initiate a flow. Interestingly, most agents are placed short of the bladder neck, within the smooth muscle layer in the zone of the continence mechanism. Klarskov and Lose measured pressure and cross-sectional area in the urethra of women with SUI and mixed incontinence before and after urethral injection therapy, using a pressure profile reflectometer [11]. This novel technique detected a significantly greater increase in squeezing opening pressures in patients who had subjectively noted an effect. They suggested that injection therapy functions as a central filler volume that increases the length of muscle fibers and thereby the power of the urethral sphincter. The external sphincter consists of muscle fibers, collagen, vessels, and nerves, with a central component compressing the lumen [12]. An increased central filler volume will augment the sarcomere length of muscle fibers, strengthening muscle power up to a sarcomere length of 2.2 μm [13, 14].

## Economic considerations

Rising healthcare costs and an aging population requiring greater medical care has led to an interest in clinicians evaluating the economic considerations associated with surgical interventions. Given the variety of different surgical treatments available for SUI and its prevalence within the general population, a rigorous understanding of the economic aspects of treatment represents an area which could yield significant economic benefit. Each year, the estimated direct cost associated with the treatment of SUI is in excess of US$12 billion [15]. A recent cost utility analysis of midurethral sling (MUS) compared to UBAs over a 1-year timeframe demonstrated that MUS cost US$436 465 more than UBAs per 100 women treated with an estimate that MUS was cost effective at a cost of US$5132 or less and cost saving (less expensive than UBAs with improved outcomes) at a cost of US$2035 or less [16]. Although MUS demonstrated a greater reported rates of dryness at 12 months (65% vs. 38.7%) within this model, the increased initial costs with MUS as well as a higher rate of significant complications (sling excision, repeat sling, erosion) led the authors to conclude that over a short-term follow-up that UBAs may be a cost-effective treatment for 47.6% of patient while MUS is only cost effective in less than 1% of patients [16]. Although this study relied on a theoretical model based on previously reported outcomes, patients would benefit from a prospectively designed trial of UBAs versus MUS which includes economic analysis as a key design outcome. This is particularly important given a recent study that demonstrated significant variation in reporting surgical outcomes with less than 40% of studies utilizing validated questionnaires in reporting surgical outcomes for SUI [17]. Greater utilization of validated questionnaires for surgical outcomes are a critical component for accurately assessing the economic impacts of SUI and the available surgical treatments.

## Patient selection

The index patient for bulking should have demonstrated stress incontinence and evidence of intrinsic sphincter deficiency (ISD). While there exists some argument over a fixed versus a mobile urethra, most would agree that a relatively fixed urethra (nonradiated) may respond well to bulking. The patient with hypermobility may have some improvement, but usually the shearing force of a cough is too great to maintain dryness if mobility exists. The traditional inclusion criteria for bulking agents are patients with poor urethral sphincter function with isolated ISD (defined as urodynamically confirmed abdominal leak point pressures $<100\,\mathrm{cmH_2O}$), limited urethral mobility, and an absence of detrusor instability [18]. Presently, the European Association of Urology (EAU) guidelines on SUI recommend the consideration of periurethral injection treatments in women with stress incontinence or mixed urinary incontinence, stress predominant symptomatology [19]. This indication is based on the fact that support is a key factor to consider in urethral bulking. Specifically, if there is poor vaginal support and significant mobility of the bladder neck/urethral complex, other options usually have been thought to deliver better results. However, as UBAs were more widely adopted, some clinicians have investigated their role in patients with urethral hypermobility. Herschorn et al. in Toronto demonstrated that the patient with hypermobility could derive benefit from UBA treatment [20, 21]. In fact, no significant difference in outcomes was seen in patients with or without hypermobility in their studies. Interestingly, patients with hypermobility required less collagen for a successful outcome. Similarly, Monga et al. reported on 60 women with genuine stress incontinence and urethral excursion ("mobility") of up to 25 mm [22]. Objective cure rates (according to urodynamic assessment) were 61% at three months and 48% at 24 months. Subjective success rates were 86% and 68% at three months and 24 months, respectively. A logical conclusion derived from these studies is that ISD can exist in the presence of hypermobility and that this alone should not be a criterion for exclusion from bulking therapy. There is, of course, a gray area, where the patient and physician agree to use these agents fully anticipating a partial improvement in an otherwise poor surgical candidate. A key element to remember from the current EAU guidelines is an "A" recommendation not to offer periurethral bulking agents for women who desire a permanent cure for SUI [19]. Finally, in addition to physical examination, urodynamic studies need to be performed to document a low leak point pressure, as well as to rule out other sources of incontinence. Video urodynamics may be helpful for directing visualizing the bladder neck and proximal urethra, but is not necessary to confirm low urethral resistance.

Ultimately, good patient selection with a careful preoperative assessment as well as management of preoperative patient expectations about the duration and degree of efficacy with UBAs are critical for obtaining the best possible patient outcomes and satisfaction with this intervention.

## Techniques

There have been numerous approaches to placement of UBAs, including intraurethral or transurethral, periurethral, and even transvaginal [23–25]. The two most common routes are transurethral or periurethral, with the former being the most commonly utilized approach. Yet, two transurethral techniques evolved for a short time: the obvious visual approach and a "blind" technique. The nonendoscopic approach was designed ostensibly to eliminate operator variability. First described by Henalla et al., a device was developed to control the placement of the injected material in predetermined areas [26]. This technique is rarely used today in the United States, likely due to the additional cost of the implantation system and the familiarity and ease of injection by urologists with the transurethral and periurethral techniques.

Both transurethral and periurethral techniques utilize visualization with an injection system scope or a female cystourethroscope to aid in guiding the injection of the bulking agent. After the bladder is drained, the scope is placed mid urethra. Most techniques describe needle placement at 4 and 8 o'clock with a submucosal injection. The trial with Macroplastique™ added an injection at the 6 o'clock position. The goal of the injection is to achieve either horizontal or concentric coaptation of the bladder neck and proximal urethra. The bulking agent should be injected relatively slowly to allow for tissue accommodation and to prevent extrusion of injected bulking agent. For the transurethral injection, a transurethral needle is placed through the scope, whereas the periurethral technique uses a spinal needle placed alongside the urethra through the vaginal wall.

Faerber et al. reviewed the outcomes and differences between the transurethral and periurethral routes of injection [23]. There were no statistically significant differences in outcome, although current guidelines state that there is a higher risk of postoperative urinary retention with percutaneous access as required for the periurethral approach [19]. In a prospective study by Schulz et al., the authors concluded that both periurethral and transurethral methods were comparable [24]. However, the amount of material utilized was much greater in the periurethral group, which would, of course, drive the expense of the procedure upward.

Many patients require additional treatments and various waiting periods are required for each unique agent. Postoperatively, a small amount of bleeding or bulking agent leakage can be noted for 1–2 days. Retention can occur and should be treated with 24-hour catheterization with a small 8–10 Fr Foley or clean intermittent catheter technique to avoid molding the newly injected material. Urinary retention is usually self-limiting. If prolonged retention is apparent, then a suprapubic tube should be considered to avoid crossing the urethra which has been treated. Moreover, it is not uncommon to have temporary irritative urinary symptoms. Stothers et al. reported a 12.6% incidence of *de novo* urge incontinence in a large prospective trial [27].

## Materials

The ideal injectable agent should primarily be safe (i.e. biocompatible, nonimmunologic, and hypoallergenic). It should retain its bulking characteristics for a prolonged interval and not biodegrade or migrate, but it should also be easily explanted or degraded if necessary. In addition, it should be easy to prepare and implant. In the United States, there are presently three available injectable bulking agents approved by the FDA. These are calcium hydroxylapatite particles in a gel carrier (Coaptite™), carbon-coated zirconium beads (Durasphere™), and polydimethylsiloxane (Macroplastique™). Internationally, polyacrylamide hydrogel (Bulkamid™) is another bulking agent that is widely used. For many years, the most commonly utilized and studied bulking agent was glutaraldehyde crosslinked bovine collagen (Contigen™), however this agent was voluntarily withdrawn from the market by its manufacturer in 2011. Given the prevalence of collagen, many head-to-head trials with other currently available bulking agents were performed as comparison trials to collagen. However, presently there is no evidence that any available bulking agent provides superior outcomes [19].

### Calcium hydroxylapatite (Coaptite)

Calcium hydroxylapatite (Coaptite) is a synthetic injectable implant composed of smooth calcium hydroxylapatite bioceramic microspheres that have a diameter range of 75–125 μm, suspended in an aqueous gel carrier. A normal constituent of bone, it is also nonimmunogenic, and was previously used in dental and orthopedic surgery. A 12-month prospective, randomized, comparative, multicenter, single-blind, parallel, clinical trial of calcium hydroxylapatite and collagen for soft tissue augmentation of the urethral sphincter in the treatment of SUI enrolled 296 women. Essentially comparable results, 63% and 57% improvement, respectively, were reported [28]. Approved by the FDA in November of 2005, it is used for the treatment of ISD. Some serious side-effects have occurred with Coaptite that were reported in the Mayer et al. study: one erosion through the vaginal wall and one injection which dissected into the bladder, causing a tissue bridge to form [28]. In addition, urethral prolapse has been reported in a delayed fashion months after injection [29].

### Carbon-coated zirconium beads (Durasphere)

Carbon-coated zirconium beads (Durasphere) is a sterile, nonpyrogenic injectable bulking material composed of pyrolytic carbon-coated graphite beads suspended in a 97% water, 3% beta-glucan carrier gel. It is inert and nonimmunogenic, and therefore does not require skin testing, unlike collagen which requires a skin test within 30 days of injection to assess for hypersensitivity. In a head-to-head trial, Durasphere and collagen were randomized to similar patients. The Durasphere group showed an improvement of 1 or more Stamey grades in 80% of patients compared to 69% in the collagen group. Although this analysis demonstrated a trend favoring Durasphere over collagen, there was not a statistically significant difference improvement [30]. One theoretical concern with Durasphere was phagocytosis and migration of bead particles as it is known that macrophages can phagocytize particles of less than 80 µm, which could result in transportation throughout the body. To address this concern, the carrying gel was re-engineered as Durasphere EXP, with an optimized bead size of 90–212 µm. Although Durasphere beads should not migrate because of their size, it is possible that the zirconium beads found in lymphatics and other ectopic locations may result from high-pressure injection. Durasphere is safe and has no risk of allergy. Results have been comparable to those with collagen, but the immediate complications with it are slightly higher, as reflected in the rate of urinary retention, but this rarely persists or requires surgical intervention [31].

## Polydimethylsiloxane (Macroplastique)

Silicone (Microimplants, Macroplastique, and Bioplastique) is a soft, flexible irregular material made of vulcanized polydimethylsiloxane macroparticles or simple silicone rubber. The silicone particles are inert, biocompatible, nonbiodegradeable, and nontetratogenic. The mean particle size is 100–300 µm, limiting the chances of migration via phagocytosis. The material, however, must be injected with a special injection system because of its high viscosity. The material was approved by the FDA for treatment in SUI. Reported cure and improvements rates are 60% and 80%, respectively [32, 33]. Complications are similar to those with other agents and include transient hematuria, retention, and urinary tract infection. Henly and others have expressed concern about small particle migration; however, this is not a common outcome [34]. In a multicenter randomized trial between Macroplastique and collagen, 61.5% of the former agent improved by 1 or more Stamey grades, in contrast to 48% of the collagen group. A total of 36.9% of patients in the Macroplastique group were dry compared with 24.8% of the collagen patients [30]. A recent review and meta-analysis demonstrated improvement rates of 75% for short-term (<six months) results, which were reasonably durable over long-term follow-up, with 64% of patients reporting improvement for long-term (>18 months) results [35].

### Polyacrylamide hydrogel (Bulkamid™)

Bulkamid UBA is a crosslinked synthetic polymer of polyacrylamide hydrogel that is available internationally but has not yet been approved by the FDA in the United States. A unique aspect of this agent is a homogeneous composition of the agent as it does not contain any particles. In the original clinical trial on the use of this agent by Lose et al., eight patients (38%) were subjectively dry and a further nine (43%) improved [36]. Objectively, urine leakage/24 hours decreased by 93% and the number of incontinence episodes decreased by 87% [36]. Quality-of-life measures improved significantly in all domains other than general health perception. There were no significant changes in urodynamic variables. The most commonly reported treatment-related adverse events were urinary tract infection and urinary retention [36]. The 2-year follow-up data from this trial reported stable response outcomes to their 1-year data. At 2 years of follow-up, although there was a relatively low cure rate of 17%, a majority (64%) reported either cure or improvement in symptoms for a relatively robust sample of 135 patients [37]. The results of the North American trial were recently published that compared Bulkamid to collagen with a 2:1 allocation. In this study, 50% of the 229 women treated with Bulkamid reported zero stress incontinence episodes at 1 year and 77.1% of women reported cure or improvement [38]. These results were noninferior to those for patients randomized to collagen treatment.

### Other agents

There have been attempts to use other materials, including dermal collagen implants, autologous fat, and even autologous chondrocytes [39]. A systematic review of randomized trials for noninvasive anti-incontinence procedures included seven randomized controlled trials (RCTs) on a total of 882 women implanted with different injectable bulking agents [40]. The overall level of evidence was classified as low. Rates of continence and improvement were similar among the different agents in most of the RCTs. Curative effects were shown after intraurethral collagen injection in women with SUI (51.5% were dry during a 24-hour pad test) [41]. Transurethral injection of a porcine dermal implant resulted in a negative pad test results (i.e. cure) in 60% of women with urodynamically proven SUI [42]. Transurethral injection of the bulking agent dextran copolymer resulted in objective cure in 15% of women with stress or mixed incontinence (minor and controlled urge component) in whom previous conservative treatments had failed [24]. Only one RCT reported statistically significant relative benefit. This benefit was seen in 63 women with SUI at 12-month follow-up. A literature review by Chapple et al. concluded that quality-of life improvement after urethral injections appears to be significant and is comparable to that obtained with surgery, despite the observation of superior objective surgical efficacy [43].

## Future agents

Although the currently available UBAs are chemical polymers, the future of these treatments may be found in the field of tissue engineering, particularly with stem cells. Autologous stem cells are an especially appealing treatment option as they have no risk of immunological reaction because they are derived from the patient. The role of stem cells in promoting antiapoptotic, antiscarring, and neovascular effects and ability to replenish cells in case of injury could be an ideal treatment for SUI and ISD [44]. However, this field has not been without controversy. One study by Strasser et al. [45] that initially garnered significant attention and promise looked at using injections of autologous myoblasts and fibroblasts for urinary incontinence. Although the results were promising, closer scrutiny of the technology and numerous inconsistencies in the documentation, records and a lack of ethics approval for this trial resulted in suspicion over the veracity of these results and a subsequent withdrawal of the paper by the *Lancet* [46].

Since this study, several other investigators have performed trials utilizing tissue engineering to create hybrid bulking agents with significant promise. Shi et al. [47] published their results of a tissue-engineered bulking agent created with adipose-derived stem cells and silk fibroin microspheres, which demonstrated improvement in urethral function in a rat ISD model with both neo-tissue and nerve regeneration noted after treatment with this novel bulking agent. Similarly, Watanabe et al. [48] were able to demonstrate increased urethral resistance and increased leak point pressures following injection of autologous derived adipose stem cells in a rat model. In addition to adipose-derived stem cells, investigators have looked at muscle [49], urine [50], and bone marrow [51] as potential sources for stem cells to improve urethral function.

Although these therapies have not yet been translated to clinical practice, these results are an exciting frontier in regenerative medicine that may lead to a safe and effective minimally invasive approach to treating SUI.

## Conclusions

The role of UBAs has evolved over the last two decades in parallel to the developing technology of slings. As a result, they are more frequently used in patients with multiple medical comorbidities whose increased surgical risks prevent them from having open surgery. Moreover, once considered a primary treatment, today these agents are best used as an adjunct to a failed sling or other anti-incontinence surgery. They can improve the quality of life for a subset of patients. The search for a better injectable agent continues as the fields of biomaterials and regenerative medicine now look to better understand SUI.

## Introduction

Stress urinary incontinence (SUI) is a condition that affects the psychosocial welfare, interpersonal relationships, quality of life, productivity, and general health of afflicted women. Its prevalence has been reported to be from 14% to 46% in women older than 18 years of age [1–3]. The prevalence of SUI in women peaks at middle age and then declines slightly in favor of mixed urinary incontinence (MUI) and urge urinary incontinence (UUI) thereafter [1, 2, 4, 5]. Despite this significant prevalence, due to the invasive nature and associated prolonged recovery of surgical options offered in the past, many women did not undergo treatment.

Since Ulmsten and Petros described the tension-free vaginal tape (TVT, Ethicon, Somerville, NJ, USA) procedure in 1995, "An ambulatory surgical procedure under local anesthesia for treatment of female urinary incontinence" midurethral synthetic slings (MUSS) have grown in acceptance and popularity to gain a leading position in stress urinary incontinence surgery [6]. They have become a new gold standard for the surgical treatment of female SUI, not only because of their simplicity for both the surgeon and the patient, but also because of excellent surgical outcomes and low morbidity. There are numerous studies, both randomized controlled trials and well-designed prospective studies, which provide a large amount of level 1 and 2 evidence that supports the concept of a sling placed at the level of the midurethra. In addition, there is growing evidence regarding how different approaches for placing a MUSS (retropubic and transobturator) can be applied to specific patient groups. This evidence base will be reviewed to help resolve clinical dilemmas concerning the selection of candidates for MUSS.

In this chapter we also describe the anatomic basis and techniques of MUSS, examine their indications and outcomes in select patient populations, describe "less invasive" techniques, and discuss the management of complications that can occur after MUSS placement.

## Determining which patients are candidates for MUSS

Patients who could or should have MUSS placed are those with uncomplicated SUI or mixed incontinence with urethral hypermobility. The MUSS is the most widely studied procedure with SUI and has very low morbidity and complication rates. The American Urogynecologic Society (AUGS)/Society of Urodynamics, Female Pelvic Medicine and Urogenital Reconstruction (SUFU) Position Statement on Mesh Midurethral Slings gives "full support" to their use, calling attention to the fact that mesh midurethral slings (MUS) have been extensively studied with positive short- and long-term outcomes demonstrating "superior safety and efficacy" [7]. There are three unique complications of mesh that may require reoperation: extrusion, pain, and erosion.

Patients for whom placement of MUSS is questionable are those with a fixed urethra. Slings have been found less effective in women without urethral hypermobility [8]. This is discussed further in the section on intrinsic sphincter deficiency.

Patients who should not have MUSS placed include women with prior mesh erosion or two failed prior MUSS, women undergoing simultaneous urethral reconstruction, women with neurogenic SUI and the goal of clean intermittent catheterization (CIC), and finally patients with a preference to avoid synthetic mesh.

Two good alternatives exist for these patients, the pubovaginal sling (PVS), in which a strip of mesh or fascial tissue is placed under the urethra to provide support and compression, and Burch colposuspension, in which an abdominal approach is taken to attach the paravaginal fascia to Cooper's to suspend and stabilize the urethra.

## MUSS: anatomy and surgical technique

### Mechanism of action

The theoretical basis for the original TVT procedure was the "integral theory of female urinary continence" based on a series of anatomic studies of the female urethral closure mechanism performed by Petros and Ulmsten in the 1990s [9]. An important alternate theory advanced by DeLancey in 1994 is his description of the "hammock theory" [10]. Both of these theories strive to explain how urethral pressure can be maintained above vesical pressure during increased intra-abdominal pressure. In the integral theory this is explained by opposing forces; the pelvic floor muscles act through their vaginal attachments to stretch the vaginal hammock against the pubourethral ligaments, shutting the urethra off from behind. Weakness in the pubourethral ligaments would lead to similar forces opening the urethra. The more practical "hammock theory" proposes that both urethral support and constriction are important. In this model the support is provided by the layers outside the urethra on which it rests: the anterior vaginal wall, the endopelvic fascia between the arcus tendineus facia pelvic on each side, and pelvic floor muscles. With increased intra-abodominal pressure the urethral remains shut against this backboard, as long as it is intact. When the backboard is not intact, urethral hypermobility and/or SUI may result. It has been shown by ultrasound studies that placement of a sling at the midurethral level causes a dynamic kinking of the urethra with stress and thus can cure stress incontinence without affecting position or urethral mobility [11].

### Anatomic approaches

**Retropubic MUSS (see Video 162.1)**

The original TVT procedure placed polypropylene sling at the level of the midurethra via a "bottom to top" approach (Figure 162.1). This involved the passage of a trocar from a midurethral vaginal incision through the endopelvic fascia and the retropubic space to a suprapubic exit point. The "top to bottom" technique was developed in 2001 [12] with the introduction of the Suprapubic Arc system SPARC (SPARC, American Medical Systems, Inc., Minnetonka, MN, USA) sling. This technique involved passage of the trocar from a suprapubic incision (lateral to the midline) to a subepithelial vaginal dissection. Subsequently, there have been a number of different modifications of the bottom to top and top to bottom approaches using minor modifications of sling material and surgical instrumentation.

**Transobturator MUSS**

The transobturator approach was introduced by Delorme in 2001 [13] to avoid trocar passage in the retropubic space/pelvis addressing concerns over bladder, bowel and major vessel injury, and voiding dysfunction following TVT (Figure 162.2). In this approach vaginal dissection is performed as per the retropubic approach. The original transobturator tape (TOT) operation was described as an "outside-in" technique with the tape being passed from the thigh into the vaginal incision (Uratape, Porges-Mentor, Le Plessis, Robinson, France). In 2003, DeLeval further modified the technique as an "inside-out," approach with a vaginal incision in through the obturator foramen and out the inner thigh as the TVT-Obturator (TVT-O, Ethicon, Somerville, NJ, USA) [14]. Both transobturator approaches involve trocar passage between the vaginal incision, through the obturator membrane and obturator internus muscle to a groin incision below the adductor muscle insertion.

### Types of mesh

A number of different synthetic materials have been used as slings over the past decades. Both monofilament

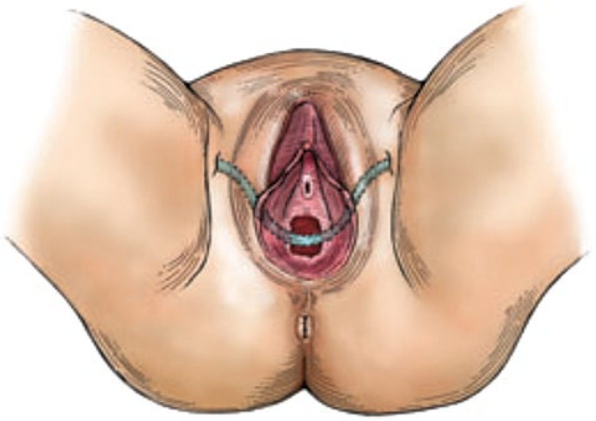

**Figure 162.2** Transobturator tape *in situ*. *Source:* Bullock TL. Advances in female stress urinary incontinence: mid-urethral slings. *BJU Int* 1999;98(s1):32–40. Reproduced with permission of John Wiley & Sons Inc.

and multifilament materials have been tried. The ideal sling material should be inert, nonallergic, and relatively resistant to inflammation and infection. Synthetic meshes are divided into four groups: type 1 – macroporous, monofilament; type 2 – microporous; type 3 – macroporous, multifilament; and type 4 – submicronic, coated biomaterials with pore sizes of <1 μm. Since the introduction of the MUSS, it has become clear that slings made from type 1 mesh are superior to other slings, predominately because they are relatively resistant to infection and inflammation. Slack et al. [15] showed in an *in vivo* study that type 1 mesh had an early and sustained filling with fibrous connective tissue and capillaries showing that macroporous meshes promote tissue host in growth with resultant integration allowing anchoring of the mesh within the tissue. The inflammatory response provoked decreases markedly with time, thus reducing the risk of infection. Both type 2 and 3 meshes had a much more marked inflammatory response without as much fibrous ingrowth. Obtape in particular had barely any fibrous tissue or capillary ingrowth. These findings are in concordance with several other studies that support type 1 mesh as having optimal qualities for use in suburethral slings [15]. The largest trial comparing monofilament and multifilament slings was published by Meschia et al. of 190 patients randomized to TVT or intravaginal slingplasty (IVS). At 24 months follow-up only vaginal erosion was significantly more common after IVS than TVT [16]. In 2005, Domingo et al. reported a 13.8% extrusion rate for the ObTape [17]. Based on the above animal and clinical studies, all commercially available MUS are now made from type 1, noncoated mesh (Table 162.1). Of note, in 2008 the US Food and Drug Association (FDA) released a warning on the safety of vaginal mesh for prolapse repair and SUI that raised significant concern among patients concerning the use of mesh. This was amended in July 2008 when the FDA released an Update on the Safety and Effectiveness of Vaginal Placement for Pelvic Organ Prolapse that applies specifically to pelvic organ prolapse repair [18]. In 2013 the FDA released another statement that multi-incision, midurethral polypropylene slings are safe and effective [19].

## Surgical technique

### Retropubic MUSS

The down-to-up and up-to-down techniques are described. Ulmsten's original technique described the use of intravenous sedation to allow for an intraoperative cough test and adjustment of sling tension [6]. This is not always employed now, so that general, regional, or sedation may be used.

**Table 162.1** Some commonly used commercially available type 1 mesh slings.

| Name | Type | Manufacturer |
|---|---|---|
| Tension-free vaginal tape (TVT) | Retropubic "Bottom to top" | Ethicon Inc., Somerville, NJ, USA |
| Advantage | Retropubic "Bottom to top" | Boston Scientific Inc, Maple Grove, MN, USA |
| Lynx | Retropubic "Top to bottom" | Boston Scientific |
| Prefyx PPS | Prepubic "Bottom to top" | Boston Scientific |
| ObTryx | Transobturator "Outside-In" | Boston Scientific |
| Aris | Transobturator "Outside-In" | Coloplast A/S, Copenhagen, Denmark |
| TVT-Obturator (TVT-O) | Transobturator "Inside-Out" | Ethicon |
| Ajust | Single Incision | Bard Medical Division, Covington, GA, USA |
| Solyx | Single Incision | Boston Scientific |

Adapted from [20].

The crucial steps of the down-to-up procedure (modified from Ulmsten's report [21]) are as follows:

1) The bladder is emptied at the outset of surgery. This allows passage of trocars around an empty bladder, reducing the chance of bladder perforation.
2) Local anaesthetic can be injected in the path of trocar placement and just below the vaginal epithelium to facilitate dissection in the correct anatomical plane beneath the epithelium but above the periurethral fascia.
3) A 1.5 cm midline longitudinal vaginal incision is made, beginning approximately 0.5 cm proximal to external urethral meatus but not extending to the bladder neck to avoid bladder neck obstruction with the sling.
4) The subepithelial plane is dissected laterally from the midline vaginal incision to the endopelvic fascia, minimizing disruption of structures through which the sling will pass. A space large enough to insert an index finger to palpate the endopelvic fascia is made.
5) A stainless-steel catheter guide is placed within the Foley catheter allowing identification of the urethra and bladder neck during trocar passage. This may also help to position the bladder neck for trocar passage.
6) The trocar with attached sling is placed within the previously dissected subepithelial plane. The endopelvic fascia is perforated and the trocar is guided into and through the retropubic space. Close contact with the back of the pubic bone (and avoidance of lateral deviation) is ensured so as to avoid vascular or visceral injury.
7) A small suprapubic incision is made bilaterally just above the pubic bone, about 2 cm lateral to the symphysis pubis, and the trocars exit here.
8) Cystoscopy is preformed with a full bladder to make certain that there is no bladder or urethral injury. If there is an injury the trocar is removed and repositioned.
9) The trocar and attached tape are pulled up and the sling is placed at the level of the midurethra without tension (a Hagar dilator, clamp or pair of scissors can be used beneath the sling to prevent overtightening).
10) In the awake patient, a cough test may be performed to help adjust tension.
11) The casing of the tape is removed.
12) The vaginal wall is closed.
13) The excess tape is excised at the level of the skin incisions on both sides and these are closed.

In most cases a catheter is not necessary postoperatively.

The up-to-down technique is very similar except that the trocars are placed from the suprapubic incision downwards [12]. The vaginal incision is performed as described above. After bilateral paraurethral dissection of the vaginal wall, two small horizontal suprapubic incisions are made, no more than 2 cm lateral to the midline, for needle entry. The needle is grasped with one hand on the handle and the other hand on the curved portion of the needle, near the abdominal incision, to control the direction of the needle tip. Then the needle is passed through one of the suprapubic incisions, down the posterior side of the pubic bone toward the vaginal incision. The needle tip should remain in contact with the posterior pubic bone until it is passed through the endopelvic fascia. Using the index finger of the other hand, the surgeon locates the tip of the needle, then guides it through the vaginal incision. With the first needle in place, the surgeon inserts the second needle on the contralateral side, in the same way [12]. Cystoscopy is performed to check for a bladder or urethral injury. The sling is attached to the end of each trocar and pulled up through the suprapubic incision. The sling is tensioned.

### Transobturator MUSS

As with retropubic MUSS a number of similar devices have been introduced, both outside-in [13] and inside-out [14]. Anatomical studies have shown that in this method the synthetic sling is entirely outside the pelvis (and also retropubic space), within the foremost extension of the ischiorectal fossa [22, 23]. For outside-in placement, the vaginal dissection is performed as per the original TVT operation. A puncture incision is made 15 mm lateral to the ischiopubic ramus on a horizontal line level with the clitoris. The trocar is held in the same hand as the side on which the operator is working. It is held vertically with the handle downwards; it is then introduced through the skin incision and crosses the obturator membrane. As the membrane is crossed, a specific resistance is felt and the handle is rotated to allow palpation of the tip on the finger within the vaginal fornix [24].

The inside-out technique differs in that a small introducer is placed beneath the vaginal epithelium and perforates the obturator membrane. The trocar is then introduced into its grooved surface and rotated 90° toward the thigh, exiting a skin incision made at the level of the clitoris and below the adductor longus tendon. For both techniques it is important that the trocar (and tape) exit/enter the obturator foramen at its superior-medial border, away from the obturator vessels. TOTs tend to tighten when the casing is removed, therefore extra care needs to be taken to avoid this. Although the risk of bladder and urethral perforation are lower for transobturator versus retropubic sling placement, it is not zero. Therefore we recommend performing cystoscopy after all transobturator sling placements to ensure that the bladder and urethra have not been injured.

## Results of midurethral slings

Comparisons of outcomes in incontinence surgery are hampered by variations in definition of success. Definitions of cure may be subjective, where the patient reports absence of stress incontinence, preferably by a validated questionnaire or instrument, or objective, where the absence of incontinence is proven by a negative cough or pad test. In addition, various levels of subjective and objective improvement may constitute success depending upon the study protocols. Long- and intermediate-term data are now available from a number of MUSS trials that provide level 2 evidence for durability of treatment. Long-term data has been published for the original TVT procedure from Nilsson et al. [25]. Their most recent publication provides level 2 evidence with mean follow-up of 16.75 years of 58/90 (78.4%) of patients in their original series. Objective cure, defined in this group as negative cough test, was found in 91.3% of women. Only one woman from the cohort had a further stress incontinence procedure. Subjectively, 87.2% considered themselves cured or significantly better than before surgery based on the Patient Global Impression of Improvement (PGI-I). Long-term data are now also available for the transobturator technique. Liapis et al. recently reported follow-up at 4 years for TVT-O with a cure rate of 82.4% in 74 patients and Waltregny and colleagues reported follow-up at 3 years for the original TOT series described by DeLeval, with a cure rate of 88.4% [26, 27].

Perhaps the best way to describe the results of MUSS is to look at the level 1 and 2 evidence of various randomized controlled and comparator trials. These trials compare MUSS to other surgical procedures. Most of these studies contain “index” patients, which are patients with SUI only and evidence of urethral hypermobility. Here we discuss the use of slings in patients other than these patients and present the evidence regarding their success in these groups. There have been several high-quality reviews of the literature on synthetic slings. A recent Cochrane review by Ford et al. found 81 randomized trials including synthetic slings [28]. These included comparisons between retropubic top-down versus bottom-up approach, transobturator outside-in versus inside-out, and retropubic versus transobturator route. An earlier Cochrane review by Rehman et al. included comparisons between synthetic slings and traditional sling operations or colposuspension [29]. Prior to this Novara et al. had reviewed the complication rates in a meta-analysis published in 2010 [30].

### Comparison trials of MUSS to other surgical procedures for SUI

Initial level 1 evidence for TVT comes from the Ward and Hilton trial, a multicenter randomized controlled trial of TVT versus Burch colposuspension. In the original publication, the authors showed TVT and colposuspension have equivalent efficacy (based on very strict criteria with losses to follow-up considered failures) with 51% cure for TVT versus 63% for Burch [31]. The authors also reported 5-year follow-up data on 117 patients [32]. For the primary efficacy variable of a negative 1-hour stress pad test, there was no difference in success (81% vs. 90%). Furthermore, secondary variables of cure of stress leakage (63% vs. 70%), and satisfied or very satisfied (91% vs. 90%) showed no difference. Hospital stay was significantly shorter for the sling group. There was no difference in the chance of reoperation. However, patients who had colposuspension were more likely to require prolapse surgery (7.5% vs. 1.8%). The authors did note that identifying true durability of cure was somewhat hampered by loss to follow-up across both groups as only 119 of the original 377 patients had full 5-year subjective and objective data sets. A subanalysis of the trial by Manca et al. showed that TVT was more cost-effective than Burch colposuspension, with greater gains in quality-of-life (QOL) years gained [33].

The Cochrane review found 12 randomized trials comparing MUSS to traditional slings [28]. MUSS had a shorter operating time (42 versus 102 minutes) and shorter hospital stays (RR 0.49). Different QOL measures were used in each study, but all showed similar outcomes for traditional versus synthetic slings. For open colposuspension versus traditional slings seven randomized trials were included. Objective cure rates at 12 months ($N = 729$) were 79% for synthetic slings versus 82% for colposuspension. For laparoscopic colposuspension versus slings, the combined results of six trials showed no significant difference in patient-reported outcomes within 12 months; 80% for slings versus 74% for colposuspension. By clinician assessment there was a significant difference in favor of synthetic slings (89% vs. 78%).

### Comparator trials for retropubic MUSS

The Cochrane review found three trials reported on patient-reported cure (defined as absence of leakage on stress) showing a significant difference in favor of bottom to top versus top to bottom at 12 months (87.34% versus 79.58%) [28]. The combined analysis of objective cure rate in five trials (by pad test or stress test) also favored bottom to top by a smaller margin (94.2% vs. 89.1%).

### Comparator trials for transobturator MUSS

There are eight randomized studies that directly compare “outside-in” to “inside-out” transobturator slings [34–41].

These demonstrate equivalent cure rates over the short and medium term; objective cure rates range from 83% to 98% for outside-in and 87% to 90% for inside-out. By subjective measures, most often the PGI-I, inside-out ranged from 76.7% to 100% and outside-in from 77.3% to 97.9%. Similarly in Latthe et al.'s meta-analysis of transobturator slings, indirect comparison of TVT-O and TOT showed equivalent cure rates [42].

### Comparison of retropubic and transobturator approaches

One meta-analysis compared retropubic with transobturator slings with medium-term and long-term results. Tommaselli et al. found 49 eligible studies, both randomized and cohort, with a minimum of 36 months follow-up [43]. In total, 1200 patients were in randomized and 5206 were in cohort studies. When the cohort studies were considered, there was an 83.2% success rate for the retropubic and an 83.5% for the transobturator approach. The pooled estimates for objective cure were similar for retropubic and transobturator with odds ratio (OR) 1.15, 95% confidence interval (CI) 0.75–1.76. The pooled odds ratio for subjective cure in three randomized studies reporting this was 1.76 (95% CI 1.08–2.86) in favor of the retropubic approach. The authors attribute the higher subjective cure rate with retropubic approach to one study that defined success as the absence of reoperation for recurrent SUI on request by the patient [44]. When the cohort studies were included there was 72.7% subjective cure in the retropubic versus 82.1% in the transobturator. The authors caution that differences in long-term subjective cure rate may be confounded by recall bias, including new onset of urgency incontinence unrelated to the original procedure.

In the recent Cochrane review, Ford et al. reviewed 55 trials that compared retropubic and transobturator approaches of MUSS placement [28]. Subjective cure was reported in 36 trials with a total of 5514 participants, and showed no statistically significant difference between routes. In 40 trials with 6145 participants, women were slightly less likely to be objectively cured when using the transobturator route (85.7%) compared with the retropubic route (87.2%); although there was no significant difference, the relative risk for objective cure rate was 0.98 at 12 months. Similarly Latthe et al. found a total of 14 trials comparing either TVT-O or TOT to TVT, showing no difference in subjective cure rate [45]. Sung et al. [46] in a review of 6 randomized controlled trials and 11 cohort studies in 2591 women showed no difference in subjective failure between the two routes; 5.7% for transobturator versus 7.8% for retropubic in randomized controlled trials and 15.4% for transobturator versus 12.8% for retropubic in cohort studies. They did, however, note a lower risk of complications and *de novo* irritative voiding symptoms for the transobturator group. They concluded that it would take a randomized controlled trial of 30 000 women to demonstrate superiority of one approach over the other.

An important study recently characterized long-term outcomes after retropubic and transobturator slings [47]. In this study, women who had been randomized in the TOMUS trial to retropubic or transobturator slings were evaluated at 5 years for treatment success, defined as no retreatment or self-reported stress incontinence symptoms. In total, 404 women (68% of the original cohort) participated. The authors found that there was a 7.9% greater success rate in the retropubic sling compared to the transobturator (51.3% vs. 43.4%, 95% CI 1.4, 17.2). Patients with a retropubic sling also reported greater urinary urgency ($P = 0.001$), more negative impact on QOL ($P = 0.02$) and worse sexual function ($P = 0.001$), however. The authors noted that while both arms reported worsened urinary symptoms and QOL with time, there was no statistically significant difference in satisfaction with high satisfaction for both retropubic (79%) and transobturator slings (85%) at 5 years.

Based on these studies it appears that for the index patient the retropubic MUSS offer slightly higher efficacy over time with perhaps a slight advantage to the transobturator approach with respect to intraoperative and long-term complications.

## Results of MUSS in special populations

### Mixed incontinence

With any SUI operation in the patient with mixed symptoms, there are always concerns about lower cure rates for the stress component and persistent urgency and urgency incontinence for the overactive bladder component. With respect to cure of SUI, studies on MUSS have shown varied results. A systematic review of seven prospective studies found that patients with MUI had an overall subjective cure rate of 56.4% [48]. The overall cure for SUI varied from 85% to 97%, while urgency and UUI were present in 15–75% at up to 5 years follow-up. The authors also performed a meta-analysis on six randomized trials that included women with MUI and found no difference in subjective cure whether retropubic or transobturator MUS was used, regardless of the presence of detrusor overactivity on urodynamics. Nilsson's update of his original series in 2001 included 59 (of 161) patients with MUI, but no detrusor overactivity. At a mean follow-up of 16.7 months, the cure rate for MUI patients (81.4%) was not statistically different from those with pure stress incontinence (88%) [49]. In contrast, a recent retrospective cohort study of 534 women who underwent primary MUSS surgery for SUI reported that those with MUI, defined by at least "moderately" bothersome stress and urgency incontinence, were less likely to have successful improvement in SUI than women with SUI only (64% vs. 84.5%) [50]. These results were calculated from the Urogenital Distress Inventory (UDI-6) subscale that all women completed before and after surgery. Of note, women with MUI had greater improvements in the UDI-6 than those with SUI only, indicating substantial improvement in their urinary symptoms and QOL.

To further stratify patients with MUI, a study of 1113 patients compared those who presented with predominant stress, equal stress and urgency, and predominant urgency incontinence [51]. Preoperative urodynamic parameters, including detrusor overactivity, were not reported in this study. Overall outcomes in these MUI populations were good; 87.3% and 82.7% were stress test dry at 7 and 38 months of follow-up. These authors had strict standards for cure; for subjective cure this was both being very satisfied and having stress and urgency indices of 2 or less on standardized questionnaires, while objective cure had to include negative stress test, pad test <10 g. There was no difference in rates of "stress test dry" at 7 and 38 months between groups, though there was a trend to lower cure rates for urgency-predominant incontinence at 38 months (75.3% compared to 84.7% for stress-predominant incontinence). There were, however, statistically significant differences between objective, subjective cure, pad test dry, and patient satisfaction for stress-predominant versus urgency-predominant patients at 7 and 38 months, with urgency-predominant incontinent patients worse in all parameters. These authors also found that compared with preoperative status, rates of urgency incontinence deteriorated between 7 and 38 months. Holmgren et al. [51] also showed deterioration over time in 2–8 years follow-up. Women with pure stress incontinence maintained a cure rate of 82% to 8 years, whereas women with MUI had a lower cure rate at 60% to 4 years, with a further decline to 30% at 4–8 years after surgery.

Overall, these results suggest that women with mixed incontinence can do well with sling surgery with respect to SUI, but they should be carefully counseled that urge symptoms can persist, with significant impact on patient satisfaction. We believe that women should not be excluded for MUSS surgery based on the presence of urgency incontinence or symptoms.

## Obesity

There is one prospective randomized study that has examined obesity as an independent variable across different surgical procedures to treat SUI, though this was a secondary analysis [52]. The authors found no difference in cure for obese women between TVT and TOT, though this analysis was limited by sample size. They did find a significant difference between nonobese women compared to obese women for both objective (85.6% vs. 67.8%) and subjective (85.8% vs. 70.7%) cure rates. Stav et al. performed a multivariate analysis on 1225 women following MUS that revealed that body mass index (BMI) >25 kg/m$^2$ was a significant predictor (OR 2.9) for MUS failure (along with mixed incontinence (OR 2.4), previous incontinence surgery (OR 2.2), intrinsic sphincter deficiency (ISD) (OR 1.9), and diabetes mellitus (OR 1.8)) [53]. Seven published studies have shown no decrease in cure after TVT, whereas five studies showed a difference [52]. Another retrospective study by Killingsworth et al. reviewed outcomes of TVT at 1 year by PGI-I, UDI-6, and Incontinence Impact Questionnaire (IIQ-7), finding no differences in satisfaction, improvement in QOL, and complications between three groups of normal (BMI <25 kg/m$^2$) overweight (BMI 25–30 kg/m$^2$) and obese (BMI >30 kg/m$^2$) women [54]. A single study by Hellberg et al., where 970 women post-TVT were telephone surveyed at mean follow-up 5.6 years, showed significant differences in cure from 81.2% in BMI <25 kg/m$^2$ to 52.1% cure in BMI >35 kg/m$^2$ [55]. However, this study did not control for preoperative symptom severity and did not use a standardized questionnaire. A more recent study, specifically for transobturator slings in obese (BMI 30–34 kg/m$^2$) and severely obese (BMI ≥35 kg/m$^2$) women reported that at follow-up of at least 12 months, there was no significant difference in failure of TOT, but on subgroup analysis severely obese patients were more likely to have postoperative UUI [56].

## Elderly

The effect of age on outcomes of MUSS is relatively undefined. There are a number of confounding variables such as a higher rate of detrusor overactivity and ISD in the elderly. Also the definition of elderly varies between studies. At best we can say that there is conflicting evidence regarding age and its impact on MUSS outcomes. Liapis et al. showed a cure rate of 76.4% in 55 patients with a mean age of 75.4 years [57]. Pugsley et al. showed a cure rate of 77% for women over 70 years compared to 92% for those younger than 70 years who underwent TVT or colposuspension; however, there was considerable disparity in number with only 22 in the older group versus 100 younger than 70 [58]. Sevestre et al. demonstrated a cure rate of 67% in 76 patients with a mean age of 76 years [59]. Hellberg et al. also analyzed their results in TVT for the "very old" versus other patients, finding a reduced cure rate of 56% for those above 75 compared to 80% for those below 75 years [55]. Conversely, in the retrospective study mentioned above by Stav et al., age was not found to be a risk factor for MUSS failure [53]. Gordon et al. demonstrated similar cure rates between younger (mean age 57.8, $n = 208$) and older (mean 74.9, $n = 123$) patients undergoing TVT at 12 months by absence of persistent stress incontinence at 6% and 7%, respectively. A significant difference between these groups was the frequency of concomitant prolapse repair, at 81% for older women and 67% for younger women [60]. Two other studies also showed equivalence in TVT [61, 62]. Malek et al. showed no difference in SUI failure rates between older (mean age 75.4, $n = 160$) and younger (mean age 56.2, $n = 536$) women [63]. Interestingly, they found the younger patients reported a greater impression of improvement compared to older women (67.7% vs. 56.6%). Campeau et al. compared immediate to six-month delayed placement of TVT in 69 women aged >70 years. At six months, the sling group had improved QOL and patient satisfaction compared to the delayed group [64].

Perioperative morbidity and complications are also a consideration in older patients, with several authors showing higher rates in elderly patients. The study by Gordon et al. [60] showed the risk of *de novo* urge was 18% at 1 year in older versus 4% in younger patients. Also in the elderly group there were 2 cases of pulmonary embolism, 2 cases of cardiac arrhythmia, 1 case of severe pneumonia, and 1 case of deep vein thrombosis versus the younger group, where none of these occurred except one cardiac arrhythmia. Pugsley et al. showed that there were higher rates of patients requiring intermittent self-catheterization, urinary tract infection (UTI), and division of tape (OR 29) [58]. Campeau et al. [64] showed significant perioperative complications: bladder perforation (22.6%), urinary retention (12.9%), urinary tract infection (3.2%), and *de novo* urgency (3.2%). At present there are no studies that report on transobturator slings specifically in an elderly population.

## Recurrent stress incontinence

There are several studies that specifically address surgery for recurrent stress incontinence after failed transobturator or retropubic or mini-slings. On meta-analysis of 14 studies of MUS placement after failed anti-incontinence surgery, Pradhan et al. determined that the repeat retropubic approach was significantly more successful than repeat transobturator approach (79.8% vs. 54%) [65]. They found overall reported cure rates based on objective measurements, such as cough stress test or pad test, for repeat MUSS placement to be 73.3%. Liapis et al. [66] published a series of 31 such patients. They found the overall cure rate when placing a TVT in patients with recurrent SUI was 74%. However, it was best (>80%) in those who had urethral hypermobility and no ISD. Success was reduced but satisfactory (63%) with low urethral mobility (<30°) and no ISD, and was low (40%) with both ISD and a fixed urethra (40%). Meschia et al. included 25/301 patients with previous anti-incontinence procedures in their series using TVT, in which they demonstrated a lower cure rate of 72% for recurrent versus 89% for primary treatment [67]. A review by Stav et al. [68] comparing outcomes of repeat and primary MUS slings in over 1000 patients found 65% subjective success in repeat slings compared to 86% in patients undergoing primary sling placement ($P < 0.001$). They also showed that a repeat retropubic was more successful than a repeat transobturator sling (71% vs. 48%). Both of these results may in part be due to the higher rate of ISD in repeat candidates (31% vs. 13%). Also of note, the rates of *de novo* urgency (30% vs. 14%) and *de novo* urgency incontinence (22% vs. 5%) were higher in the repeat group. The EAU Guidelines on Surgical Treatment of Urinary Incontinence recommends that before a repeat sling procedure is performed, the patient should be warned that the outcome is likely to be inferior to first-line treatment, with chance of both an increased risk of harm and reduced degree of benefit [69].

## Concomitant prolapse surgery/hysterectomy

Groutz et al. published their series of 100 clinically continent women with occult SUI with prolapse reduction [70]. At mean follow-up of 27 months, results were comparable with "index" patients. Only two patients had symptomatic SUI at 1 year. In addition, perioperative morbidity was low, with only two patients requiring catheterization of more than 7 days and *de novo* urgency in 8%, which is comparable with sling-only series. Liang et al. reported a series of patients undergoing hysterectomy and prolapse repair who underwent pessary reduction of the prolapse during preoperative urodynamic testing [71]. Patients with a positive pessary test (occult SUI) were randomized to TVT or no TVT. The rate of postoperative subjective SUI was significantly lower in those who had a TVT placed (10% vs. 65%). No patients with a negative pessary test (none of whom had a sling) had postoperative SUI. A previous prospective trial with 3-year follow-up by Meltomaa et al. found that concomitant vaginal surgery did not affect the outcome of TVT, but there was an increased rate of complications such as infection, bladder perforation, and transient retention after TVT [72]. Ballert et al. [73] used urodynamics to decide which patients should have a MUSS placed with prolapse repair. Patients who had urodynamic proved SUI and occult SUI (with the prolapse reduced, SUI demonstrated during urodynamic studies) had a MUSS placed. The OPUS Trial was designed to address the issue of prophylactic sling placement at the time of prolapse repair in women without SUI [74]. In this trial 337 women were randomized to TVT or sham incisions and the authors found that the rate of *de novo* SUI was significantly higher in the women who did not receive the TVT (27.3% vs. 43% at 12 months). Although the benefit was higher for women with occult SUI, a benefit was seen even in women who had a negative preoperative prolapse reduction stress test. Based on the currently available literature, it would appear that MUSS is a good choice to treat concomitant SUI and prolapse, and is effective in reducing the risk of postoperative SUI in women with occult SUI.

### Intrinsic sphincter deficiency

ISD represents the portion of SUI that is not due to a support defect or urethral mobility. ISD is difficult to quantify and even more difficult to diagnose in patients who also have urethral mobility. Most of the literature has used a definition of an abdominal leak point pressure (ALPP) of $<60\,\text{cmH}_2\text{O}$ or a maximum urethral closure pressure (MUCP) of $<20\,\text{cmH}_2\text{O}$. While we would agree that these lower resistance urethras are probably more difficult to treat, it is difficult to say that the lower resistance is due to true ISD rather than a support defect (except in the fixed urethra). Nevertheless the literature has made that distinction and for the purpose of this review we will accept that as "ISD," but prefer to use the term "low ALPP." More recently, ISD and urethral hypermobility have been viewed as a spectrum of disease with overlap. Thus recent research examines the contributions of ISD and urethral hypermobility to outcomes.

Patients with low ALPP are more likely to develop recurrent SUI after MUS than those without low ALPP [68]. Retropubic MUSS have been shown to be effective in treating this group of patients. Rezapour et al. [75] reported on their long-term results in patients with low ALPP, defined as MUCP $<20\,\text{cmH}_2\text{O}$, at 2 years, with cure rates of 74%, 12.5% improved, and 12% no change. These results compare favorably with their and other author's results for all comers with SUI. There are eight studies reporting data specifically for women with low ALPP which favor retropubic over transobturator MUSS and one RCT [76] showing equivalence in patients with low ALPP [77]. Fritel et al. [8] showed that TVT was most effective in treating the hypermobile urethra but had acceptable success rates for the relatively fixed urethra. Success rates at nine months were 97% with Q-tip test >60°, 86% for Q-tip test 30–60°, and 70% for Q-tip test <30°. There was no difference in success based on MUCP greater or less than $20\,\text{cmH}_2\text{O}$. A small study ($n = 65$) by Haliloglu et al. [78] of urethral hypermobility (Q-tip test >30°) and low ALPP (ALPP $<60\,\text{cmH}_2\text{O}$) with TOT found that cure rates at 24 months (defined as a negative cough test) were: urethral hypermobility, no low ALPP 96.4% ($n = 31$); urethral hypermobility and low ALPP 87.5% ($n = 18$); and no urethral hypermobility and ALPP 66.7% ($n = 16$). They concluded that a lack of urethral hypermobility may be a risk factor for TOT failure and suggested that even in the presence of low leak point pressures suggestive of low ALPP, the coexistence of urethral hypermobility still indicates likely good outcomes with transobturator MUSS.

The literature suggests that patients with low ALPP may do better with retropubic MUSS but the evidence is not strong enough to support a high-level recommendation. Since urodynamic studies are no longer recommended for uncomplicated SUI, and thus ALPP will not be determined in these patients, one might lean toward a retropubic MUS in cases of a more fixed urethra.

## Single-incision slings

Although the retropubic and transobturator MUSS are considered minimally invasive procedures, efforts have been made to make the procedures even less invasive. The single-incision slings or "mini-slings" were designed to be placed via a small vaginal incision (like the traditional MUSS) but without any exit incisions. They sit like a hammock (mimicking the transobturator slings) or like a U (mimicking retropubic slings).

A number of single-incision slings were brought to the market through the FDA's 501 k process. There was promise that single-incision slings would yield easier implantation with lower complications and quicker recovery, but this has not been borne out in early trials. In 2012 following a series of lawsuits concerning the mesh slings, some prolapse repair kits and single-incision slings have been removed from the market. Currently, several single-incision slings are still available, but they do not have long-term outcomes [79–81].

A recent Cochrane review analyzed 31 peer-reviewed studies including 3290 women that compared single-incision slings to traditional MUSS [80]. Of note, many of these trials studied the TVT-Secur, which is no longer available. They found higher rates of incontinence after surgery with single-incision slings compared to both retropubic (RR 2.08) and transobturator (RR 2.55) slings. When compared to retropubic slings, the reported duration of surgery for single-incision slings was slightly shorter, but risk of *de novo* urgency was higher (RR 2.39). The analysis also found higher rates of adverse events such as lower urinary tract injury, postoperative voiding difficulties, mesh erosion, *de novo* urgency, or worsening of preexisting urgency with the single-incision slings. This difference disappeared when the TVT-Secur was removed from analysis, but groin pain rate was significantly lower with the single-incision sling (RR 0.30). The authors report that when studies including the TVT-Secur were removed from analysis there was insufficient evidence to show a difference between single-incision slings and transobturator slings or to compare the other single-incision slings to each other.

More high-quality trials are needed to determine whether the single-incision sling is equivalent to the retropubic and transobturator. Available data are short- and medium-term only, with mixed results. Further research is also required to determine whether there are differences between the many available single-incision slings still available.

## Complications of MUSS and their management

Here we outline the incidence of complications and briefly discuss management for intraoperative complications (bladder, urethral, bowel, and vascular injury), immediate postoperative complications (voiding dysfunction and obstruction, groin pain, infection), and chronic problems (obstruction requiring surgical intervention, *de novo* urgency, sling erosion/extrusion).

### Intraoperative complications

#### Bladder perforation

Bladder perforation occurs at approximately 3.4% during TVT [30]. Transobturator slings were conceived to reduce the risk of bladder (and vessel) injury by avoiding the retropubic space. Three reviews have confirmed this. The recent Cochrane review found 40 trials reporting on bladder perforation and pooled data to show that TOT had significantly lower rates of bladder injury than retropubic slings (0.6% vs. 4.5%) [82]. Novara et al. [30] showed that in analysis of nonrandomized data, TOT was statistically less likely to cause perforation than retropubic slings and Latthe et al. showed in their meta-analysis of trials comparing TVT-O and TOT versus TVT the ORs of bladder injury were 0.11 and 0.15, respectively [42].

Bladder perforations recognized intraoperatively can be managed by removal of the tape and replacement of the tape. Cystoscopic confirmation that the final position is indeed outside the bladder is crucial.

Urethral injury is a rare occurrence with both retropubic and transobturator MUSS. Like bladder injuries, they are treated by removing the tape. In cases of a large injury, consideration should be given to aborting the procedure and allowing urethral healing for three months before inserting a new sling.

#### Vascular and bowel injuries

An important paper was published by Deng et al. in 2007 regarding the reporting of major complications after MUS surgery [83]. They reviewed the literature and compared this to reporting through the FDA Manufacturer and User facility Device Experience (MAUDE) database queries for self-reported complications for the same time period. Their review of the world literature 2001–2005 found the rate of major complications to be 0.8% with no reported deaths. In the MAUDE database from the United States 928 total complications were reported in that time period, including 161 major complications with 10 resulting in death. Notable differences were noted, with 36 serious vascular injuries and 38 bowel injuries in the MAUDE database but only 2 vascular and 3 bowel injuries in the literature 2001–2005.

Vascular injury occurs very rarely but this is a devastating complication for a QOL procedure. The MAUDE database was discussed and published by Deng et al. in 2007. National registries provide the best indicators of worldwide incidence and are summarized in a case report and literature review by Sivanesan et al. for 2006 [84]. The incidences of vascular injury reported include: 0 (of 1455) in the Finnish registry, 0.8% (from 5578) reintervention or conversion rate in the Austrian registry, 0.03% (of 2280) in the French registry, and 0.1% of 809 in the Netherlands registry [85, 86].

Management depends on the patient's hemodynamic status. In those who are stable angiographic embolization avoids further operative morbidity, while those who are unstable may require laparotomy and control of bleeding.

Bowel injury is also a very rare complication in the literature, estimated at less than 1%. Two were reported in 12 280 cases in the French registry for TVT [86]. Ten cases were reported after TVT in the FDA MAUDE database in Daneghasri's review of complications in 2008 [87]. Six deaths had resulted from bowel injury. No cases of bowel injury have been reported after TOT.

### Postoperative complications

#### Voiding dysfunction and obstruction

Voiding dysfunction is reported at varying levels after sling surgery. A population-based cohort study of 188 454 women who had a MUSS calculated the postoperative risk of urinary retention to be 0.9% at 1 year, with a cumulative 9-year risk of 2.5% [88]. The recent Cochrane review found that transobturator slings had a lower incidence of voiding dysfunction than retropubic (RR 0.53, moderate quality evidence) [82]. The TOMUS trial reported equivalent outcomes with retropubic compared to TOT at 12 months, but by 2-year follow-up the incidence of voiding dysfunction was significantly higher, with retropubic sling at 3% compared to 0% with transobturator placement [89].

Symptoms of *de novo* urge may be secondary to urethral obstruction and while not an absolute indicators in themselves of voiding dysfunction, refractory symptoms with timing associated with intervention or association with voiding symptoms should alert the clinician to the possibility of obstruction. It is especially important to document the relationship of symptom onset to surgery. If patients report symptoms of voiding dysfunction, a free flow rate should be measured. The necessity of urodynamics in this setting is controversial. We would not consider them always necessary in the setting of classic obstructive voiding symptoms, retention, or high postvoid residual (PVR) (with normal preoperative PVR) [90]. However, video-urodynamics would be useful in patients with storage symptoms to determine whether obstruction is present at the level of the sling.

Conservative management includes observation for irritative/storage symptoms and clean intermittent selfcatheterization for high PVR and retention.

With respect to timing of sling loosening or cutting, we favor an approach of early tape loosening for severe obstructive symptoms and retention. Several small series now suggest that early intervention should be favored as delayed intervention may lead to irreversible bladder symptoms. Leng et al. published a series of 21 patients who underwent sling lysis. When they stratified patients by their postoperative symptoms or absence of symptoms, there was a statistically significant difference in mean time to sling lysis: 9 months in the no symptom versus 31 months in the persistent symptom group [91]. South et al. showed a similar trend, although their series had relatively small numbers of synthetic slings [92]. Nguyen published a series of 10 women who underwent tape loosening (under anesthesia) at 3–10 days with all spontaneously voiding after this and no recurrence of obstruction or SUI at 1-year follow-up [93]. Price et al. published their series of 33 women who had early sling loosening (mean 7.7 days) under general anesthesia. This was successful in 29 women, with 4 requiring tape division at 4–8 months. All patients had resolution of voiding symptoms with 1 of the 4 tape division patients having the only recurrence of stress incontinence [94]. In contrast, a recent retrospective review of 63 patients who underwent sling revision did not find a significant difference in outcomes in women who underwent early (revision compared to late with 13% of the early group and 11% of the late group experiencing persistent voiding dysfunction) [95]. However, this study defined early as <1 year, which included patients with significantly longer time to removal than the other studies mentioned.

We consider intervention for patients who have retention or near retention at 1–2 weeks. For early intervention, sling loosening in the office or operating room can be considered. We perform this procedure in a similar fashion under local anesthesia in the office and have found this to be well tolerated. After injection of local anesthesia, the incision is opened by removing the prior closure suture. The sling is hooked with a clamp and the clamp is spread. If this fails to loosen the sling, it can be cut. Animal studies have shown fibroblast infiltration of the tape at one week, which supports Price et al.'s observation that tapes cannot be loosened after 2 weeks [94]. At this point, it is easiest to cut the tape in the operating room setting.

### Groin pain

Groin pain may occur after transobturator sling but has not been noted after retropubic slings. In the systematic review by Latthe et al. this occurred in 12% in the transobturator group compared to 0.9% in the TVT group (OR 8.28). Similarly, the Cochrane review found 6.4% incidence of groin pain in the TOT group versus 1.3% in the retropubic group (RR 6) [82]. The differential diagnosis of persistent groin pain after TOT includes adductor muscle strain, osteitis pubis, obturator/groin abscess, structural adhesions, and inflammation, edema or nerve entrapment of the anterior branch of the obturator nerve. There is a limited amount of literature regarding treatment of pain.

Workup should include examination and lab tests to exclude hematoma and infection. Magnetic resonance imaging can visualize edema, hemorrhage, and the obturator nerve itself; however, it cannot see the polpropylene tape nor smaller branches of the nerve. Described methods include pain medications, steroids, and excision of part or all of the sling. Hazewinkels et al. advised against delaying sling removal, as further scar tissue deposition can hamper removal and nerve damage may become irreversible [96]. Reynolds et al. described eight cases of intractable groin pain treated with complete removal of MUS arms via an extended obturator foramen dissection in conjunction with orthopedic surgery [97].

### Infection

UTI is the most common complication following MUSS placement and should be treated with appropriate antibiotics [87].

Seven cases of abscess (associated with vaginal erosion) following TOT were reported in the Austrian registry.

The authors concluded that these seemed more common after TOT than retropubic tapes, although four of the abscesses were associated with the Obtape, which is a 50 μm pore tape that has been removed from the market [98]. Infections are rare with the current type 1 macroporous meshes. Treatment requires complete excision of the infected tape.

## Chronic complications

### Obstruction requiring surgical intervention

Patients may present early, with retention as described above, or late with obstructive voiding symptoms: feeling of incomplete emptying, straining or hesitancy, needing to lean forward or stand, partial or complete urinary retention, or symptoms suggesting overflow incontinence. Obstruction requiring surgical intervention occurs in about 2% [82]. This is significantly lower than the rates of obstruction with pubovaginal sling, which was observed to be 6.2% in the SISTEr trial [99].

A few small series have been published reporting techniques and outcomes for sling loosening/lysis. Klutke et al. [100] described 17 patients (2.8% of a 600 patient series) who presented with obstructive symptoms following TVT. The time to sling loosening or cutting ranged from 6 to 228 days. Two techniques were used in this study: the "Washington University" technique used a right-angle clamp to identify the sling which was then transected or the "Minneapolis" technique, in which the sling was identified and loosened with Metzenbaum scissors with downward traction without sling transection. All 17 patients in this series had immediate postoperative relief of symptoms with ability to void. One patient had recurrence of stress incontinence.

Rardin et al. [101] described 23 patients (1.9% of 1175) who underwent TVT who had persistent voiding dysfunction. The mean interval between TVT placement and release was 17.3 weeks. In this study all tapes were transected or segmentally excised. Presenting symptoms were impaired bladder emptying in 20, 3 had severe irritative symptoms, and 7 had both. Seven patients had urethral dilation after TVT placement without resolution of symptoms. Resolution of voiding symptoms differed by symptom. Impaired emptying resolved in all cases. However, complete resolution of irritative symptoms occurred in only 30% of cases at the study endpoint after six weeks. Stress incontinence recurred partially in 26% and completely in 13% of patients.

Patients with storage/irritative symptoms should also be warned that in a study of 44 patients undergoing sling takedown or urethrolysis, two-thirds of patients with preoperative storage/irritative symptoms still had them postoperatively. Only 14 patients with suburethral synthetic slings (all TVT) were included in this study, so the numbers may not be sufficient to draw conclusions from this study alone [102].

For persistent voiding dysfunction after a MUSS has been formally cut, a formal transvaginal urethrolysis is the next step. It can be done through a midline vaginal incision. Fortunately this is rarely required.

### Lower urinary tract symptoms

*De novo* urgency can occur following sling surgery with rates ranging from 3% to 25.9%. The Cochrane review showed no significant difference in rates of storage symptoms between retropubic and transobturator slings with either short or medium term follow up [82]. It found the average short-term rate of *de novo* urgency for both groups was 8.35%. A recent review by Abraham et al. identified modifiable causes of postoperative urgency, including UTI (7.4–14.7%), bladder outlet obstruction (1.9–19.7%), perforation of the urinary tract (0.5–5%), and idiopathic 0–28% [103].

Risk of postoperative urgency or UUI was found on retrospective review of nearly 1000 patients to be higher for women with intrinsic sphincter deficiency, prior surgery for SUI or prolapse, and preexisting detrusor overactivity [104]. Holmgren et al. reported on a series at a mean follow-up of 5.6 years and discussed several important findings, such as patients with urgency will experience lower quality of life even if their stress incontinence is cured and urgency incontinence may not be reported in sling failure figures. In addition, urgency symptoms may not be transient and in fact the proportion of the group with urgency remained consistent over time [105]. The study compared women with and without *de novo* urgency and showed there were large and significant differences in QOL scores; the women with *de novo* urgency had an IIQ-7 of 28.1, as compared to 5.6 for those in the comparison group ($P = 0.0001$), and for the UDI-6 the corresponding figures were 49.6 and 13.6, respectively ($P = 0.0001$). They noted that "persistent incontinence" may not be reported as failure in many series if that incontinence was urgency incontinence (i.e. success is sometimes defined by absence of leakage on stress testing or patient-reported stress incontinence). As these authors note, urge and urgency incontinence may, in fact, be more bothersome to women in everyday life than stress incontinence. In their series, 51/67 patients with *de novo* urgency had actual incontinence episodes. Although most authors report that *de novo* urgency will be transient, these authors showed that 14.5% of women experienced this symptom with similar frequency across duration since TVT surgery (from 2 to 8 years).

Urgency caused by bladder outlet obstruction or urinary tract perforation should be treated as described above, while idiopathic postoperative urgency may be treated as idiopathic overactive bladder. A prospective study found onabotulinum toxin A to be equivalent for treatment of *de novo* urgency following MUS ($n = 49$) and idiopathic overactive bladder ($n = 53$) [106]. The exception to this is solifenacin, which was found in a recent study of 230 women to have lower efficacy for patients with *de novo* urgency following TOT compared to patients with idiopathic urgency [107]. Further work remains to be done to identify the optimum treatment of urgency following MUS placement.

#### Vaginal erosion/extrusion

Vaginal erosion/extrusion is reported at 2.09%. The Cochrane review found no significant difference of vaginal erosion in the TOT or TVT group [82]. In contrast, Latthe et al. found the transobturator path had a higher risk of vaginal injury (OR 3.58) [42]. Similar to bladder mesh erosion, some vaginal erosions may represent unrecognized vaginal perforation (especially at the vaginal fornices) intraoperatively. Symptoms of vaginal extrusion include malodorous vaginal discharge, postcoital spotting, dyspareunia (patient and partner), vaginal bleeding, and UTI.

Management of extrusion optimally involves surgical removal of that portion of the tape. Some authors have described a trial of conservative therapy with estrogen cream.

#### Sexual function

There are several studies that show equivalent results for sexual function after TOT and retropubic slings. They also demonstrate that while there are significant numbers who improve (29–32%) there are also some who deteriorate following anti-incontinence surgery (12.5–17.3%), with no difference demonstrated by Senthilhes et al. in their recent comparison between transobturator and retropubic synthetic slings [108].

#### Bladder and urethral erosion

Fortunately, erosion of MUSS into the bladder or urethra is a rare occurrence. When it is recognized, the first question that must be asked is whether it is a true erosion or a missed injury. In 14 randomized trials reviewed by Novara et al., only three trials reported on this, with rates from 0 to 1.8% for transobturator and 0–1.9% for retropubic slings. In assessment of four randomized trials with bladder or urethral tape erosion, no significant difference was seen between retropubic and transobturator sling placement (RR 0.34) with range from 0 to 2.9% [82].

Many authors believe that erosions into the bladder are actually slings inadvertently placed through or in the wall of the bladder at the time of surgery. McLennan and Melick demonstrated a learning curve with respect to bladder perforation [109]. Residents' cases were placed in groups of five; the rate of injury in the first five series was 40.9%, 30.7% in the second series of five, and 25.9% in the third series of five. The differences were statistically significant. Overall, there was a significant rate of missed perforation on cystoscopy with 35 of the 95 injuries missed by residents (37%). This emphasizes the need for thorough cystoscopic examination at the time of surgery to avoid missed perforations, which present as "bladder erosions." Such injuries may present with UTIs, bleeding, or bladder stones. Treatment requires removal of the sling from the bladder. Endoscopic techniques have been described with endoscopic scissors and lasers; laparoscopic techniques via the bladder and open excision are also used.

The mechanism by which urethral erosion occurs is probably due to dissection into the incorrect anatomical planes around the urethra if dissection is too close to the urethra or in the periurethral fascia or if the sling is placed under tension. Data from the Austrian registry reported urethra/bladder erosion at 0.5%.

A series of 14 urethral injuries following sling surgery was published by Morton and Hilton [110]. These patients had undergone TVT, TVT-O, SPARC, and TOT types of slings. Their pathologies included 6 perforation/erosion, 4 diverticulae, and 4 urethrovaginal fistulas. Most of the patients had had abnormal symptoms following sling insertion, including urinary retention, persistent incontinence or obstructed voiding. Each of these patients required reconstructive surgery, with 7/14 having significant persistence of overactive bladder symptoms, 1 having voiding difficult, and 1 persistent groin pain. These authors also performed a literature search for further cases, finding four further reports of urethral diverticulum and 15 of urogenital fistula. The authors used case series reports of urethral perforation to calculate rates of urethral perforation of 0.88% for retropubic slings and 1.09% for transobturator slings. Although the authors acknowledge that it is difficult to determine the true denominator, they conclude that the incidence of urethral injury appears no lower for transobturator than for the retropubic route. Thus they emphasize the importance of operative cystoscopy in all types of slings.

Urethral erosion requires removal of the eroded portion of sling and primary closure or urethral reconstruction with vaginal/Martius flaps.

## Conclusions

MUS have revolutionized female incontinence surgery. From their inception they offered comparable efficacy to existing operations with improved ease of performance for the surgeon and improved postoperative morbidity for the patient.

These results have proven durable in the long term. Further innovation of the technique includes the emergence of transobturator and mini-slings. Although complications of these slings are relatively rare, surgeons who perform these operations should be mindful of their symptoms so that management is expedient.

## Introduction

Urinary incontinence is a common symptom affecting almost a third of adult women [1]. It can occur due to hypermobility or intrinsic sphincter deficiency of the urethra (stress urinary incontinence (SUI)) and/or bladder dysfunction. Whatever its etiology, urinary incontinence is associated with poor quality of life and most incontinent women develop symptoms such as anxiety, depression, and social isolation over time [2, 3]. The American Urological Association (AUA) guidelines for SUI list several surgical options, of which the most common are pubovaginal and midurethral sling [4]. In 2010, approximately 560 000 women with SUI underwent surgical repair with mesh products; however, the use of various synthetic biomaterials from a variety of manufacturers gave rise to a wide range of mesh-related complications [5]. For these reasons, despite the advantages of minimally invasive procedures for SUI, use of pubovaginal fascial slings has increased over the last few years [5]. This chapter addresses the following subjects regarding pubovaginal fascial slings: indications, surgical technique, postoperative complications, and surgical outcomes.

### Historical landmarks

In 1907, Von Giordano described the use of gracilis muscle wrapped around the urethra for the treatment of women with SUI [6]. Three years later, instead of gracilis muscle Goebell used the pyramidalis muscle to improve the urethral support [7]. Autologous fascial sling was first reported by Price in 1933 when he used a suburethral strip of fascia lata for the treatment of women with recurrent SUI [8]. In 1942, Aldridge used a rectus fascia segment placed inferiorly through the rectus abdominis muscle to provide urethral support [9]. Thirty years later, in 1978 McGuire and Lytton reintroduced the concept of fascial slings for women with SUI. They used an autologous rectus fascia segment to suspend the bladder neck and promote urinary continence [10]. In 1991 Blaivas and Jacobs described midurethral slings and outlined the importance of mid urethra in urinary continence control [11, 12]. Midurethral synthetic slings were first described in 1996, with the tension-free vaginal tape (TVT) [13]. Since then, the development of different types of nonabsorbable biocompatible materials, minimal invasiveness, and availability of easy-kits has resulted in an exponential increase in the number of mesh surgical procedures performed by both urologists and gynecologists [14, 15].

### Hammock theory

The hammock theory was described by DeLancey in 1995 [16]. According to his theory the urinary continence relies on urethra and bladder neck compression by a hammock-like musculofascial layer. When this layer is deficient, funneling of the bladder neck during increased intra-abdominal pressure can result in urinary incontinence. Thus, the placement of pubovaginal slings around the mid urethra aims to provide an additional support for the continence mechanism.

## Diagnosis

By definition, SUI is an involuntary leakage of urine with effort or exertion, such as physical exercise, sneezing, or coughing. SUI is a clinical diagnosis based on a patient's history and physical examination [4].

*Smith's Textbook of Endourology*, Fourth Edition. Edited by Arthur D. Smith, Glenn M. Preminger, Louis R. Kavoussi, and Gopal H. Badlani.
© 2019 John Wiley & Sons Ltd. Published 2019 by John Wiley & Sons Ltd.
Companion website: www.wiley.com/go/smith/textbookofendourology

When urinary incontinence is not demonstrated on physical exam, additional tools such as a three-day bladder diary and pad test can be helpful. The three-day bladder diary assesses associated symptoms, such as urinary frequency and nocturia, and measures the functional bladder capacity, whereas the pad test can objectively demonstrate urinary leakage [17, 18].

Urogenital prolapse and postvoid residual volume (PVR) should be well documented prior to any therapeutic intervention. Women with prolapse can unmask occult SUI after prolapse reduction, and patients with high PVR are at risk of postoperative urinary voiding difficulty [19].

The role of urodynamic study (UDS) is still controversial in the literature. Overall, UDS is recommended by the AUA guidelines for women with mixed incontinence, significant anterior pelvic organ prolapse and SUI, recurrent SUI, patients with neurological diseases, diabetes mellitus, and those with high PVR [4, 20].

## Indications

Pubovaginal fascial slings are indicated for patients with SUI due to intrinsic sphincter deficiency and/or urethral hypermobility. They are also recommended for the following conditions [21, 22]:

- patients with prior midurethral synthetic sling who had any mesh-related complication;
- patients with urethral diverticulum and SUI;
- patients with SUI and prior pelvic irradiation;
- patients with urogenital fistula;
- patients with urethral stenosis who need urethral reconstruction.

## Preoperative preparation

Estrogen cream can be prescribed for 4–6 weeks preoperatively in postmenopausal women with vaginal epithelial atrophy if there are no contraindications. If the patient uses a pessary, it should be discontinued two weeks prior to surgery. Patients using only “baby” aspirin do not need to stop the medication prior to procedure. In the presence of urinary tract infection, coagulopathy, or other significant medical comorbidity, surgery should be postponed. All patients should be counseled about the risk of retention and recurrence. Laxative diet and fluid intake is advisable to avoid postoperative complications. Regarding antibiotic prophylaxis, first- or second-generation cephalosporin is given intravenously at least 1 hour prior to the procedure and continued for the next 24 hours [23].

## Choice of tissue/biomaterial

### Autologous fascial tissue

Autologous fascial tissue can be harvested from patient’s rectus fascia or fascia lata for sling procedures, so there is no risk of rejection. Nevertheless, the quality and strength of the tissue will depend on the patient’s age and previous surgical manipulation [24, 25]. Overall, autologous fascial slings have better long-term outcomes than Burch procedure and are comparable to synthetic slings but are associated with postoperative morbidity and convalescence [26].

**Rectus fascia**

Rectus fascia is the most common autologous tissue used in pubovaginal fascial slings. Tissue is obtained through a low transverse abdominal incision. Then dissection is carried out down to the level of the anterior rectus fascia. Following the dissection, a 1 cm × 12–16 cm fascial segment at least 5 cm above the pubic symphysis is marked with a marker pen. Two sutures are placed at either end of the fascia, perpendicular to the fascial fibers. The fascial strip is mobilized and removed carefully. Then the fascial defect is closed in a running fashion with delayed absorbable or nonabsorbable sutures.

**Fascia lata**

The main advantages of fascia lata are the lower risk of abdominal wall hernias, greater tensile strength than rectal fascia, and no previous surgical tissue manipulation. The disdvantages are that for tissue harvesting the patient needs to be repositioned, the procedure carries a risk of pain/disability, and most urologists are not familiar with the surgical field [27, 28]. The fascia lata can be harvested using different surgical approaches. We have used the technique described by Govier et al. [27]. The patient is placed in the full lateral position with the entire thigh, from the iliac crest to the tibial plateau, being prepped and draped into the surgical field. A vertical line is drawn from the greater trochanter of the femur to the lateral condyle of the knee. A 3 cm perpendicular incision is made at the midpoint of this line. Two additional perpendicular incisions of 3 cm in length are made, flanking the first incision 9 cm superior and inferior. Then the fascia lata is cleared off from the overlying subcutaneous fat. At the three skin incision sites, incisions parallel to the direction of the fascial fibers are made 2.5 cm apart. At the distal and proximal ends of the fascia, two stay sutures are placed perpendicular to the fibers of the fascia and the fascial incisions are connected to a free segment of fascia lata approximately 24 cm in length and 2.5 cm in width. After a careful hemostasis, the fascia lata is not approximated, and the

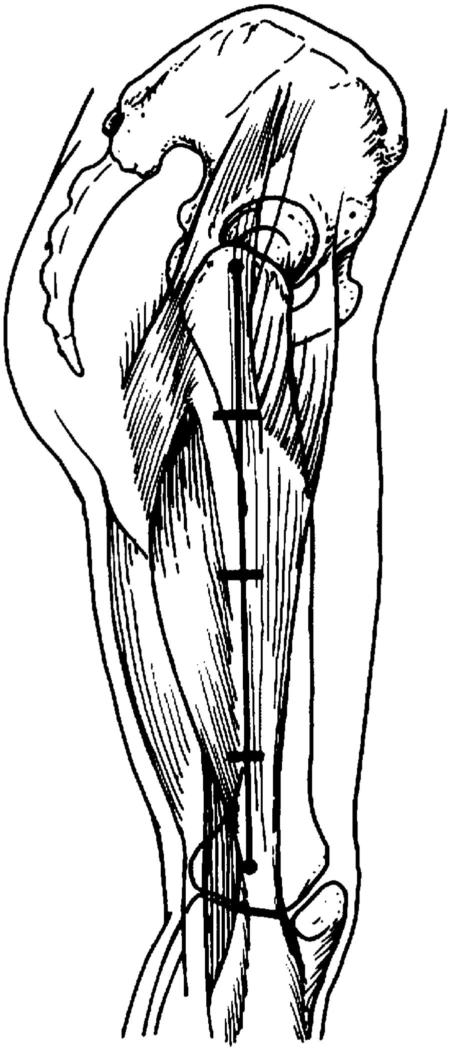

**Figure 163.1** Fascia lata – skin incisions. *Source:* Govier FE, Gibbons RP, Correa RJ et al. Pubovaginal slings using fasica lata for the treatment of intrinsic sphincter deficiency. *J Urol* 1997;157:117–121. Reproduced with permission of Elsevier.

skin is closed with a stapler. The leg is then wrapped with an elastic dressing, which is removed 8 hours postoperatively. Early ambulation is required for all patients (Figure 163.1).

### Synthetic slings

In the last decade there has been widespread use of synthetic slings. The main advantages when compared to autologous fascial slings are: (i) lower operating time; (ii) minimal invasiveness; (iii) no risk of disease transmission; and (iv) strength maintenance over time [29–31]. Monofilament polypropylene mesh with large pore size (>75 µm) is the "gold standard" synthetic biomaterial for slings. The monofilament polypropylene decreases bacterial adherence and reduces the risk of infection and foreign-body response, and the large pore size promotes mesh flexibility, facilitates host tissue integration, and allows immune cells to scavenge bacteria [31–33]. The incorporation of mesh into the sling surgical setting has decreased patient's morbidity. However, and not less important, vaginal mesh placement is associated with unique potential risks such as vaginal mesh exposure, infection, dyspareunia, and chronic pelvic pain. All of these postoperative complications should be addressed with the patient prior to the procedure [34–36].

#### Synthetic mesh substitutes

Several types of allogenic and xenogenic materials have been used as fascial sling substitutes aiming to provide readily available biomaterial without additional morbidity associated with fascia harvesting [37].

Xenografts for pubovaginal sling include material derived from porcine dermis (Pelvicol, C.R. Bard Inc., Murray Hill, NJ, USA), porcine small bowel (SIS™, C.R. Bard Inc.), and, more recently, bladder extracellular matrix. These are available as off-the-shelf biomaterials and are not used routinely for pubovaginal sling procedures. Some xenograft-related issues are the higher product costs, biomechanical variability, risk of rejection, and disease transmission [38, 39].

Like xenografts, allografts have the advantage of not requiring fascial harvesting and have similarly decreased operative times, less postoperative pain, and shorter convalescence. They are also available as an off-the-shelf material that can be used as needed. Allograft materials have lower erosion rates compared to synthetic meshes, but these advantages must be weighed against the higher cost and the risk of disease transmission [40].

## Operative techniques

After anesthetic induction, the patient is positioned in the dorsal lithotomy. The abdomen, pubis, and perineal area are shaved using clippers and then prepped with chlorhexidine-based chemical antiseptic. The patient is then draped in a sterile fashion. A 16 Fr urethral catheter is placed in the urethra and the balloon is inflated to facilitate the bladder neck identification. A 10 cm Pfannestiel incision is made above the symphysis pubis. Using cautery, the dissection is carried out through Camper's and Scarpa's fascia, and the anterior rectus fascia is identified. Using sharp and blunt dissection, the fascia is cleaned of the overlying fatty tissues. A scar-free area of the fascia at least 5 cm above the symphysis pubis is chosen. As described above, 1 cm × 12–16 cm fascial segment is marked with a marker pen. At the lateral aspect of the sling, the holding sutures are placed using 0-prolene sutures. The sling segment is carefully dissected from the rectus muscle, harvested, and placed in a saline solution with antibiotic. A Lone Star surgical retractor is used to retract the labia and open the vaginal introitus for better exposure. A weighted speculum is placed to retract the posterior fourchet. An Allis clamp is placed at the hymen ring along the anterior vagina and bupivacaine with epinephrine is injected 1 cm proximal to the urethral meatus toward the bladder neck, for vaginal tissue hydrodissection.

A 4 cm midline incision is made at mid urethra with the Foley balloon used as a guide. Metzenbaum scissors are used to dissect thick flaps of anterior vaginal wall epithelium in an anterolateral fashion, toward the ipsilateral shoulder, until the endopelvic fascia is reached. The Foley catheter and balloon should be constantly used as a guide to the urethra and bladder neck. At this point, with either the Metzenbaum scissors or blunt finger dissection, the endopelvic fascia is opened bilaterally. A packing sponge is placed in the vagina and attention is turned to the lower abdominal incision.

After emptying the bladder, a Stamey needle is passed through the anterior rectus fascia 2 cm above the symphysis through the retropubic space under digital guidance from the vaginal incision bilaterally and connected to the vaginal incision. As this surgical plane is being developed with ether blunt or sharp dissection, it is important to stay close to the posterior surface of the pubis to avoid blood vessel and bladder injuries. A cystoscopy is performed using a 70° lens to rule out any bladder injury. Bladder is emptied and catheter replaced. The sling is then placed under the proximal urethra and bladder neck, using two Stamey needles, the holding sutures on the lateral edges of the sling are brought to the abdominal incision through the retropubic space. Hemostats are placed on each set of holding sutures laterally. A 3-0 PDS or Vicryl suture is used to fix the midline of the sling, previously marked, to the periurethral tissue at 1 cm proximal and distal to the bladder neck. The vaginal incision is closed with 3-0 PDS suture and an estrogen cream-soaked vaginal pack is placed in the vagina.

The rectus fascia is then closed using 0 PDS sutures in a running fashion. The sling-holding sutures are tied to each other over the closed fascial incision. The tension of the sling sutures should be enough to place one finger between the rectus fascia and the sling sutures. The tension regulation is an important step to avoid recurrent incontinence (loose sling) or urinary retention (tight sling). Finally, the skin is closed with a 4-0 Monocryl suture. Based on the thickness of the subcutaneous tissue, a drain may or may not be used in the subcutaneous space before closing the incision (Figures 163.2 and 163.3).

## Postoperative care

A complete blood count is ordered on the morning of postoperative day 1. After reviewing the hemoglobin, the vaginal packing and the catheter are removed and the patient undergoes a voiding trial. If there is significant residual urine, the catheter is replaced for few more days and a voiding trial given as an outpatient. The patient is taught to perform clean intermittent catheterization if the retention persists on that visit. The patient is discharged to home with stool softeners and oral analgesics. She should be advised to avoid sexual intercourse and heavy lifting for the following six weeks. A follow-up visit at two weeks is scheduled to assess surgical outcomes and voiding pattern.

## Complications

### Intraoperative complications

Intraoperative complications such as bladder, urethral, or bowel injury are possible, but hemorrhage due to venous bleeding is the most common one. Although serious injuries and mortality associated with pubovaginal fascial sling are exceedingly uncommon, the surgeon must remain alert during and after the procedure to identify these potential issues and address them as they arise [41, 42].

### Harvest site complications

Patients undergoing rectus fascial sling are prone to develop postoperative hernias, while fascia lata sling is associated with leg pain or discomfort. There are a lack of data in the literature with regard to harvest site postoperative complications. Most of the data are case report or case series. For patients who develop symptomatic hernia, surgical repair is the recommended therapeutic approach. Postoperative leg pain should be managed initially with analgesics and physical therapy [43, 44]. Wound infection, especially in obese patients, or nonhealing of the wound in radiated patients is also reported [5].

### Urinary retention

Urinary retention can occur due to anatomic/functional outlet obstruction or bladder dysfunction, most commonly bladder hypocontractility. The prevalence of urinary retention after sling procedure is highly variable in the literature but higher than with Burch procedure or midurethral sling [5]. Clean intermittent catheterization or indwelling catheter should be recommended in the immediate or early postoperative period. Patients with persistent retention should be evaluated with UDS

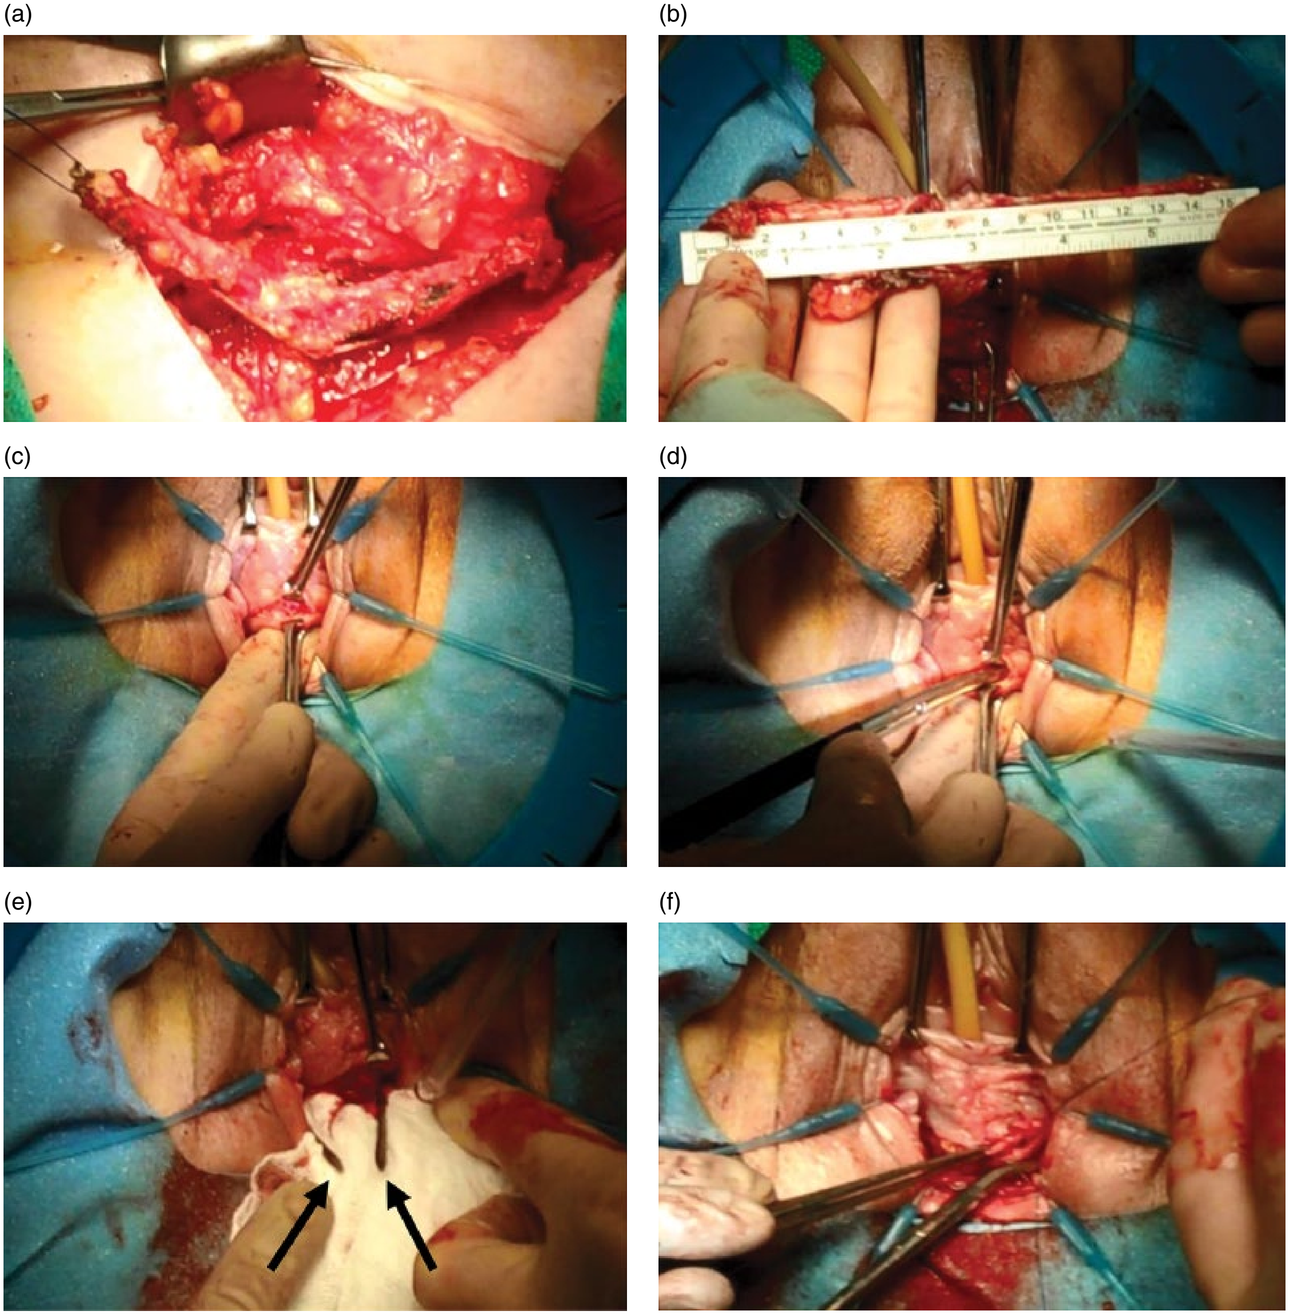

**Figure 163.2** Pubovaginal fascial sling. (a, b) Anterior rectus fascia 15 cm long. (c) Vaginal incision. (d) Dissection of the retropubic space. (e) Antigrade passage of Stamey needle (black arrows). (f) Closure of the vaginal incision.

before any further intervention. UDS findings and the patient's clinical complaints are the most important predictors to determine the therapeutic approach [45, 46].

## *De novo* urinary urgency

The incidence of *de novo* urinary urgency ranges from 5% to 40% [47]. Patients with mixed incontinence (SUI + urge incontinence) are at higher risk if compared to those with SUI only [4]. This specific group of patients should be advised about this risk before surgical intervention. If the patient develops *de novo* urinary urgency after sling placement, cystoscopy is advisable to exclude bladder perforation and obstruction needs to be ruled out [48].

The therapeutic approach depends on the patient's symptoms and how they affect their quality of life. Anticholinergic medication, pelvic floor rehabilitation, botulinum toxin, and sacral neuromodulation should be

considered as treatment options in unobstructed patients with refractory symptoms [4].

### Persistent urinary incontinence

Persistent urinary incontinence can occur in patients with urinary incontinence secondary to intrinsic sphincter deficiency (ISD) even after a sling procedure, or can be related to sling misplacement. A careful physical exam is always recommended to exclude urogenital fistula [49]. If there is no evidence of fistula, UDS is recommended before any intervention. The therapeutic approach will depend on the diagnosis; patients with severe urinary incontinence can be managed with bulking agents, repeat autologous fascial sling, or spiral slings [49].

## Clinical outcomes

In 2007 Albo et al. published the first multicenter randomized clinical trial comparing pubovaginal fascial sling and Burch colposuspension among women with SUI [26]. The primary outcomes were overall success in terms of urinary incontinence measures, which required no episodes of urinary incontinence reported in a three-day diary, negative pad test, negative stress test, no self-reported symptoms, no retreatment for the condition, and success in terms of measures of incontinence specifically, which required only the last three criteria described above. At 24 months, success rates were higher for women who underwent the sling procedure than for those who underwent Burch for both the overall category of success (47% vs. 38%, $P = 0.001$) and the category specific to stress incontinence (66% vs. 49%, $P < 0.001$). However, pubovaginal fascial sling had greater incidence of urinary tract infection, voiding dysfunction, and postoperative urge incontinence [26]. In 2012, the same group published the 5-year follow-up after Burch procedure or pubovaginal fascial sling. The continence rate decreased from 66% to 30.8% and 49% to 24.1% for sling and Burch respectively. Satisfaction also decreased with time and remained higher in the sling group (83% vs. 73%, $P = 0.04$). Ultimately, both groups had similar adverse event rates (sling 9% vs. Burch 10%) [50].

In 2011 Rehman et al. published a Cochrane review about suburethral sling operations for urinary incontinence in women. They reported that minimally invasive slings had shorter operating time, fewer perioperative complications, less postoperative voiding dysfunction, and similar subjective cure rates when compared to traditional slings [5]. Tommaselli et al. published a systematic review about medium- and long-term outcomes following placement of midurethral slings demonstrating that pubovaginal slings had similar objective cure rates but higher subjective cure rates than transobturator midurethral slings. This analysis included 11 randomized controlled trials and 38 prospective, retrospective, and cohort studies with follow-up ranges from 36 months to 10 years [19].

In 2015, Seklehner et al. published a meta-analysis which includes 2995 patients from 17 trials. The short-term objective cure rates at 16 months follow-up were 86.8% for pubovaginal slings and 83.4% for transobturator midurethral slings. Overall, pubovaginal slings were associated with higher rates of bladder perforation and bleeding (3.2%) [1].

In 2015, Kenton et al. published a 5-year longitudinal follow-up after pubovaginal slings and transobturator midurethral slings and demonstrated an objective cure rate of 51.3% and 43,4%, respectively. In both arms of the trial, patients had a significant improvement in the first years; however, urinary symptoms and quality of life worsened in a long-term follow-up [45].

## Conclusions

Pubovaginal fascial sling is an effective treatment for patients with SUI and has a high short-term objective and subjective cure rates. Although there is a clear decrease in long-term continence rates, most women report a high level of satisfaction and better quality of life after the intervention. For these reasons, it is strongly recommended that all urologists who perform anti-incontinence procedures should be acquainted with the pubovaginal fascial sling technique and its postoperative management. It remains a bail-out procedure of choice in our practice.

# Mesh Complications Associated with Vaginal Prolapse Surgery

*Jeffrey S. Schachar*[1] *& G. Willy Davila*[2]

[1] *Female Pelvic Medicine and Reconstructive Surgery, Cleveland Clinic Florida, Weston, FL, USA*
[2] *Department of Gynecology, Section of Urogynecology and Reconstructive Pelvic Surgery, Cleveland Clinic Florida, Weston, FL, USA*

## Introduction

Surgery for the correction of pelvic organ prolapse (POP) should be individualized for each patient. By the age of 80, between 6.3% and 19% of women will undergo surgery for POP, with up to a 30% risk of requiring reoperation for recurrence [1, 2]. Given the relatively high rates of prolapse recurrence following native tissue repairs, surgeons began to use surgical implants to reinforce the native tissues and achieve improved anatomical surgical success rates. Surgical mesh has been used since the 1950s for abdominal hernia repair [3]. Allografts and xenografts have been utilized, but the success of these grafts has been reported to decrease over time [4]. A Cochrane review of randomized controlled trials comparing native tissue repairs to synthetic mesh repairs found that women with permanent transvaginal mesh (TVM) repair were less likely to have recurrent prolapse and the rate of repeat surgery for prolapse was lower in the mesh groups [5].

### Mesh kits' rise to popularity

The first synthetic mesh produced specifically for incontinence and/or prolapse treatment was introduced in 1996. Because of the recognized risks of exposure and other healing abnormalities with nonabsorbable mesh, fully absorbable meshes were introduced at the end of the 1990s. Fully absorbable meshes soon became unpopular because of their poor long-term results. Trocar-guided mesh augmentation systems, or "mesh kits" first became commercially available around 2004. The rapid growth and wide adoption of mesh kits and vaginal mesh procedures after 2005 was due in large part to aggressive marketing of the available kits. In addition, approval for prosthetic devices by the US Food and Drug Administration (FDA) Center for Devices and Radiologic Health was not as strictly regulated as for medications [6]. The desire for a surgical option with improved anatomical and functional outcomes that was implanted via a standardized and "simple" approach and that was associated with decreased rates of recurrence and reoperations increased the demand for the mesh kits. General gynecologists and urologists were taught to use the mesh kits at industry-sponsored courses. Physicians who were not subspecialty trained were taught simple techniques to implant these kits, without a demonstrated comprehensive understanding of pelvic anatomy and vaginal surgical techniques [7]. Early reports led surgeons to believe that the TVM kits were associated with higher success rates and were easy to perform [8]. Soon the mesh kits were ubiquitous, until the FDA became aware of the risks associated with these procedures.

### Official statements

In 2008, as a result of over 1500 reported adverse events in a 3-year period, the FDA issued a Public Health Notification on serious complications associated with transvaginal placement of mesh to treat POP and stress urinary incontinence (SUI). In 2011, the FDA conducted a systematic review of the literature and, based on the findings, issued an update to the previous notification. They warned that serious mesh complications for transvaginal repair of POP were not rare and that the benefits of TVM repair may not be superior to traditional nonmesh repairs. In 2016, the FDA reclassified TVM for POP repair as a class III (high-risk) device. At this time the FDA does not currently have an advisory

*Smith's Textbook of Endourology*, Fourth Edition. Edited by Arthur D. Smith, Glenn M. Preminger, Louis R. Kavoussi, and Gopal H. Badlani.

Companion website: www.wiley.com/go/smith/textbookofendourology

against mesh repair for SUI (currently classified as class II – intermediate risk), but there is continued evaluation of the safety and effectiveness of these procedures. The FDA has maintained that patients with TVM who do not have complications should not undergo mesh removal [9–11].

## Materials

There is an ongoing search for the ideal graft material that has all of the benefits of permanent synthetic mesh without any of the associated adverse outcomes. The ideal graft would be made of an inert, noncarcinogenic, nonimmunogenic, strong, readily available, inexpensive, resistant to infection and shrinkage material while being pliable and available in various configurations [1, 6, 7, 12]. Until such a material is found, currently available, nonideal grafts are being used to a limited degree.

Biologic grafts, including autologous grafts (tissue harvested from the patient), allografts (tissue from a source other than the recipient but from the same species), and xenografts (tissue from a species other than that of the recipient), have several advantages and disadvantages when compared to synthetic materials. They undergo tissue remodeling after implantation and are less likely to cause vaginal epithelial erosion. This is likely due to their histological similarities with the native tissues. However, they are expensive, of limited availability, are of inconsistent strength between specimens, may be affected by chemical processing, and there is theoretical concern for disease transmission. In addition, autologous grafts increase the operative times and risks of donor-site morbidity [12]. Common donor sites for autologous grafts include abdominal wall rectus fascia and fascia lata. Allografts and xenografts avoid the donor-site morbidity associated with autologous grafts, but they are at risk for marked immune reaction and accelerated implant breakdown [6].

Synthetic grafts are available as absorbable and nonabsorbable materials. Both cause initial and chronic inflammatory reactions. Absorbable mesh elicits chronic foreign body reactions and promotes fibroblast activity. Once resorbed, the mesh material is replaced by collagen-rich connective tissue. The scar formed can weaken over time, which may not provide adequate long-term support [1, 6].

Synthetic mesh postimplantation behavior is not only influenced by the material that it is made from, but also by the pore size and the weave of the filaments. Pore size is important because it determines which cells can enter the mesh interstices. Macroporous mesh (pores greater than 75 μm in size) are large enough to allow entry of fibroblasts, macrophages, natural killer cells, blood vessels, and collagen fibers [13]. Allowing the entry of macrophages and natural killer cells helps prevent graft infection. Microporous mesh has an interfiber space of less than 10 μm, which only allow entry to bacteria and not to macrophages or natural killer cells. Similarly, multifilamentous mesh, which create lattices of less than 10 μm, have a similar disadvantage [6]. Under these circumstances a bacterial biofilm is laid around the mesh, not allowing mesh incorporation. Because of this, the best mesh implant is a lightweight, macroporous, and monofilamentous, or type I polypropylene mesh as described by Amid [14] (Table 164.1). Much recent laboratory and animal research has been directed at identifying the ideal synthetic mesh construction and weight.

**Table 164.1** Classification of synthetic meshes by Amid [14].

| Type of mesh | Characteristics |
|---|---|
| I | Macroporous (>75 μm) and monofilamentous. Can be further subdivided into heavy-, mid-, and lightweight materials |
| II | Microporous (<10 μm) |
| III | Macroporous with either multifilamentous or micropourous components |

## Complications

Immediate surgical complications related to mesh procedures, including bleeding, hematomas, and injury to adjacent organs etc. are not covered in this section as they are likely related to surgical technique and are covered in the suburethral sling chapter (Chapter 162).

The prevalence of mesh complications is difficult to determine, mostly because the true total number of patients who undergo mesh implantation and/or have mesh complications is unknown. The lack of a true denominator is likely due to a lack of systematic registration of mesh surgeries and complications and the high attrition rate of follow-up [15].

In order to better assess the nature and types of complications, it is imperative to apply specific terminology when describing mesh complications. In 2011, the International Urogynecological Association (IUGA) and the International Continence Society (ICS) convened and developed definitions as well as a standardized classification system by which mesh complications should be described. The adverse events are classified by category, time, site, and pain (Tables 164.2 and 164.3) [16].

**Table 164.2** International Urogynecological Association and International Continence Society (IUGA/ICS) definitions.

| Type of complication | Definition |
|---|---|
| Exposure | A condition displaying, revealing, exhibiting, or making accessible (vaginal mesh visualized through separated epithelium) |
| Extrusion | Passage gradually out of body structure or tissue |
| Perforation | Abnormal opening into a hollow organ or viscous |
| Dehiscence | A bursting open or gaping along natural or sutured line |
| Contraction | Shrinkage or reduction in size |
| Prominence | Parts that protrude beyond the surface (wrinkling or folding with no epithelial separation) |
| Compromise | Bring into danger |
| Separation | Physically disconnected |

Mesh-related complications can result in serious negative health impact, and frequently require surgical intervention. In a large multicenter review, about 80% of patients who had mesh-related complications underwent a surgical procedure to correct the adverse outcome. Almost 25% of patients required more than one surgical operation. Of those that were managed conservatively with medication and physical therapy, approximately 60% ultimately required surgery [17].

The Manufacturer and User Device Experience (MAUDE) database is a collection of medical device reports that are reported from physicians, manufacturers, and patients to the FDA regarding suspected device-associated complications, deaths, injuries, or malfunctions. A review of the MAUDE database from 2005 through 2010 revealed over 1700 TVM-related complications; in descending order of frequency these were mesh erosion or exposure, pain, infection, bleeding, dyspareunia, organ perforation, urinary problems, vaginal scarring or mesh contraction, neuromuscular problems, recurrent prolapse, and fistula formation [2].

Mesh exposure through the vaginal epithelium is one of the most common and well-known complications associated with TVM repair for POP (Figure 164.1). Other terms for this condition include erosion, extrusion, and rejection. The initial literature quoted the incidence of exposure to be between 0 and 33%. According to more recent review articles, the rate of mesh exposure is between 10% and 12% when implanted vaginally for repair of prolapse [5, 18]. Other reviews of level 1 evidence place the rates of exposure as high as 19% [2, 19]. Interestingly, short-term mesh exposure rates following abdominal sacrocolpopexy are significantly lower, ranging from 3% to 5%. Long-term follow-up data on sacrocolpopexy report an exposure rate of 10.5%, but about half of the mesh used in that study was made of non-type 1 mesh with known higher risk of exposure [20]. The risk of mesh exposure is higher when concomitant total laparoscopic hysterectomy is performed, reaching as high as 23%, likely secondary to the electrocautery used during the colpotomy. However, the risk drops to less than 5% if a supracervical hysterectomy is performed [21, 22]. A similar phenomenon is found with vaginal implantation, with exposure rates of up to 11.6% after six months, 17.4% after 1 year, up to 20% by 3 years, and 21% by 5 years when a vaginal hysterectomy is performed along with a TVM [23, 24].

It is crucial to understand the risk factors that are associated with mesh exposure so that patients can be appropriately counseled regarding their risks of adverse outcomes. Patients over 60 years old have a 2.2-fold increased risk, smokers a 3.7-fold increased risk, and patients with a body mass index (BMI) greater than 30 have a 30-fold increased risk of a mesh exposure [25]. Other significant factors that increase the risk of exposure include total mesh volume, experience/technique of the surgeon, severity of vaginal atrophy, concomitant hysterectomy, early resumption of vaginal sexual intercourse, diabetes, excessive mesh tension, hematoma formation, inflammation/cellulitis, infection, steroid use, placement of the mesh over a fascial plication, and an inverted “T” colpotomy [1, 4, 18, 26–28].

Pelvic pain and dyspareunia are difficult to quantify due to their subjective nature. Rates of pain anywhere from 0 to 28% are quoted [2, 19, 29], although it should be noted that studies exist showing just the opposite. Nieminen et al. found a significant reduction in dyspareunia in patients who underwent TVM repairs for anterior prolapse compared to traditional anterior colporrhaphy [30]. Mesh contraction typically presents as focal or diffuse tenderness, dyspareunia, or as prominent bands under the vaginal mucosa due to increased mesh tension. Studies have shown that polypropylene mesh can shrink up to 50% of its original length over a short period of time [31]. Regardless of the nature of the pain, the large majority of patients who undergo transection or excision of the contracted mesh segment(s) report their pain significantly reduced or resolved [2, 19].

There is approximately a 10% risk of lower urinary tract complications as a result of surgery for POP in general. When comparing prolapse repair with mesh versus native tissue repairs there is a significantly higher rate of bladder perforation (3.5% vs. 0.5%) and SUI (12.3% vs. 6.3%) in the mesh group [2, 32].

**Table 164.3** International Urogynecological Association and International Continence Society (IUGA/ICS) classification.

| Category | | | | |

## Clinical presentation and evaluation

The presentation of mesh exposure can vary greatly, from detection in an asymptomatic patient on a routine exam to dyspareunia, partner discomfort during intercourse, pelvic pain, vaginal bleeding or discharge, urgency, frequency, urinary tract infections, hematuria, dyschezia, or incontinence. The first step in any evaluation should always be a careful and detailed history. Patients do not always return to the physician who performed the initial surgery, and in such cases reviewing previous operative reports is imperative. The physician should determine the full extent of the mesh-related complication, as there may be more than one defect, implant, or complaint [29, 33].

A thorough pelvic exam should be performed, not only focusing on the area that the patient notes is the problem area. The entire pelvis should be evaluated for other possible abnormalities, of which the patient may be unaware. For patients with significant pain, a vaginoscopy may be necessary to adequately visualize the vagina for any small protruding mesh fibers. The entirety of the vagina should be palpated with one or two fingers, as the physician may be able to identify small mesh fibers from an exposure, contractures or strictures that may not be visible on speculum exam. The pelvic floor muscles should also be evaluated for focal pain or spasms. A pelvic organ prolapse quantification (POP-Q) exam should be performed to identify recurrent prolapse, shortening of the vaginal length, or vaginal stricture formation. A rectal exam should be performed in patients who underwent posterior augmentation, and office cystoscopy should be considered for those with urinary symptoms or hematuria. Polypropylene mesh can be visualized on ultrasound as a discrete echogenic area. The use of perineal or intracavitary 2D and 3D ultrasound can be crucial in the diagnosis and preoperative planning for some patients as it can identify the exact location of the mesh or if it is folded or twisted (Figure 164.2) [29, 33, 34].

It is crucial to document all the findings of an exam. While the IUGA/ICS classification system is one of the most comprehensive grading systems currently available, it is not perfect and has been criticized for being too complex and having poor interrater reliability. A standardized formula for describing and grading the severity of complications is important for interphysician communication, to allow for better assessment of the safety of the procedures, and for research purposes [33, 35].

## Prevention of mesh-related complications

The most appropriate way to manage mesh complications is to focus preoperatively on prevention. Given all of the above noted complications related to mesh, it is critical to only use mesh in the most appropriate patients and situations. Prevention starts with choosing a suitable patient, who would not otherwise benefit from a vaginal native tissue repair, biologic grafts, or an abdominal repair. There are methods by which physicians can improve their surgical outcomes preoperatively. Pessaries should be removed at least two weeks prior to surgery to reduce inflammatory reaction and improve epithelial integrity. A pelvic exam should be performed to visualize any ulceration. Preoperative administration of local vaginal estrogen cream enhances tissue integrity and can decrease risk of mesh-related complications in patients with vaginal atrophy [26, 36].

Perioperative methods to decrease risk of mesh complications start with the surgeon using optimal surgical technique. Hemostasis for prevention of hematoma-related suture line disruption is of utmost importance to prevent mesh exposure. The surgeon should consider hydrodissection of appropriate tissue planes with a hemostatic solution, maintain hemostasis throughout the procedure with sutures or minimal electrocautery use, and employ the use of vaginal packing postoperatively to minimize the risk of hematoma formation. Submucosal abscesses, for which hematomas may serve as a nidus for the infection, are also risk factors for mesh exposure. Prophylactic intravenous antibiotics should be administered at the onset of every urogynecological procedure. The volume of mesh implanted should be limited to minimize folding over and impaired tissue incorporation. The length of the incision of the vaginal epithelium should be minimized and should be closed with a full-thickness closure without tension in a nonlocking manner to allow for adequate revascularization and healing [18, 26, 36].

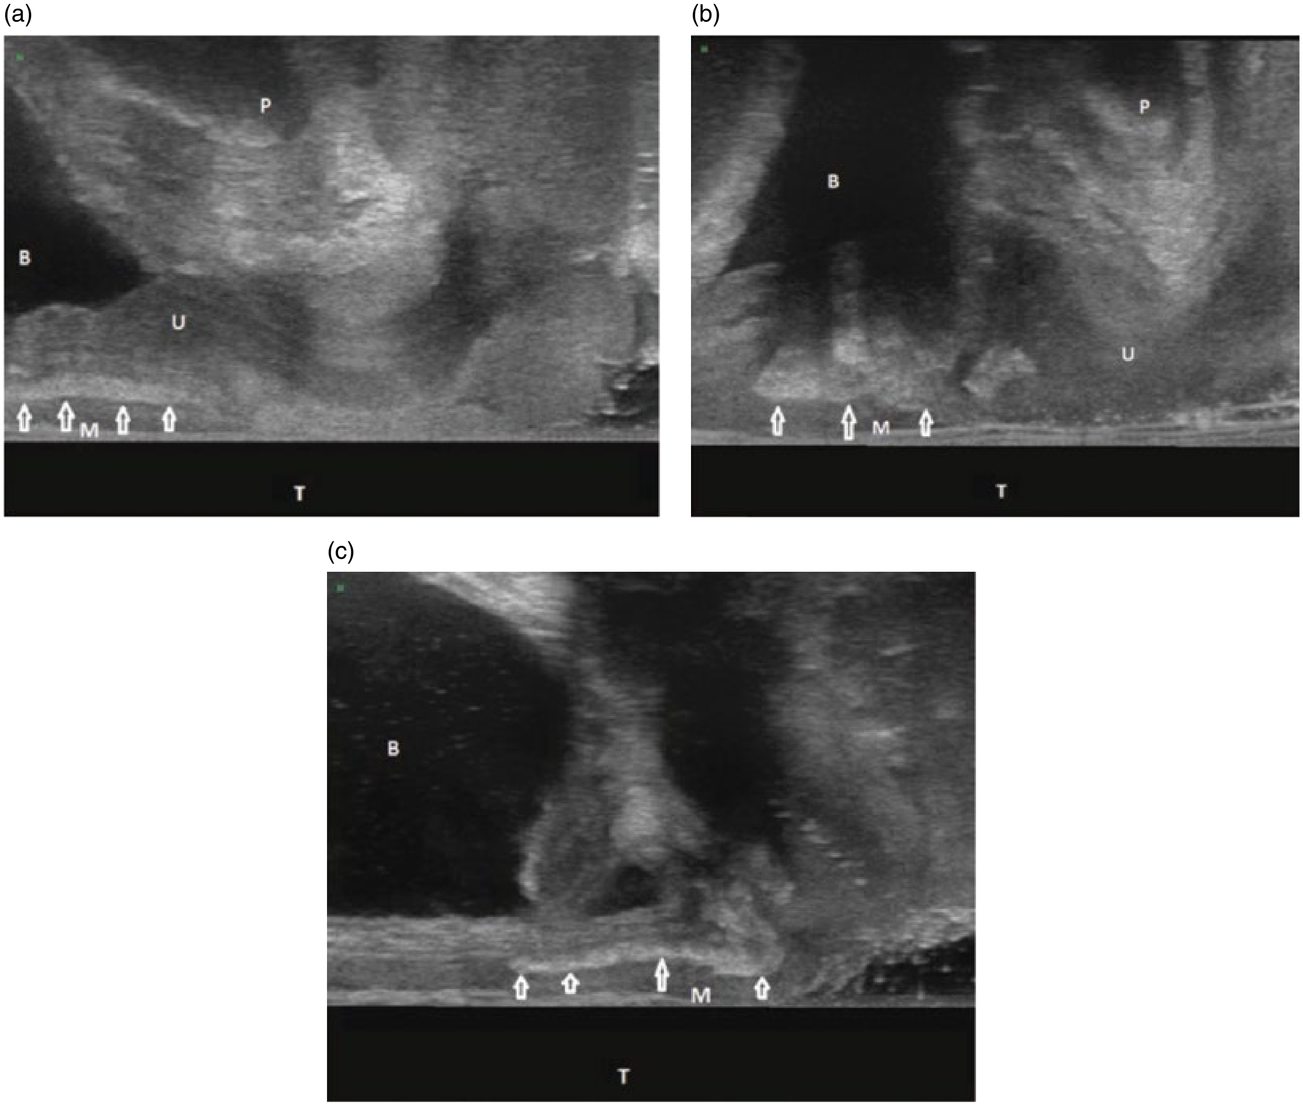

**Figure 164.2** Three-dimensional ultrasound image of sling. (a) 180° scan of the anterior compartment: mesh in the anterior vaginal wall. (b) 180° scan of the anterior compartment: mesh in the anterior vaginal wall associated with edema mesh in the anterior vaginal wall. (c) Transperineal ultrasound: mesh in the anterior vaginal wall detached from the apex. B, bladder; P, pubic symphysis; U, urethra; M, mesh; T, probe.

Finally, patients should be observed during several short-interval follow-up appointments to assess for initial signs of mesh-related complications. Early identification can help to minimize the extent of the complications. Patients should also be instructed to limit exertional physical activity for at least six weeks, including pelvic rest [36].

## Management of mesh-related complications

The management of mesh-related complications depends upon the complication, its location, severity, and impact on the patient. Mesh complications can occur in the short term, as well as many years later, so long-term follow-up is important for patients with mesh implants [15].

Conservative management with vaginal estrogen and in-office trimming is most appropriate for small exposures (<0.5 cm), if the exposure is easily reachable. With topical local anesthetic administered, the exposure should be identified and sharply excised to ensure adequate elimination of as much of the mesh as possible from the exposed area. Bleeding is typically minimal, but silver nitrate cautery can be used as needed in the office [26].

Larger (up to 4 cm) exposures are unlikely to heal with conservative management and will require outpatient surgical excision. The vaginal tissue should be prepared preoperatively with local estrogen cream to help with tissue dissection. The tissue surrounding the exposed mesh should be infiltrated with 1% lidocaine with epinephrine. Using a scalpel, the exposed area should be circumscribed with a 5 mm margin of vaginal epithelium. Dissection should continue circumferentially, undermining and mobilizing the surrounding healthy 1 cm of vaginal epithelium. The mesh, along with the 5 mm vaginal epithelial margin, should be excised with Mayo scissors. During the excision, careful attention should be paid to the mesh attachments to the underlying tissues (i.e. bladder or rectum). Depending on the width of the exposure, reapproximation of the cut mesh edges to close the defect could be attempted, with care taken to avoid creating strictures or bands. The edges of the remaining vaginal epithelium should be reapproximated without tension after ensuring hemostasis in a manner that minimizes the creation of vaginal strictures [26, 37].

Exposures that are greater than 4 cm are uncommon, most likely due to patients seeking medical care as a result of associated pelvic symptoms. However, when exposures of this size occur, it is frequently due to devascularized sloughing of segments of vaginal epithelium. The exposed mesh should be excised in a similar manner as described previously; however, it is possible that the vaginal epithelial edges may not be able to be reapproximated without affecting the vaginal length or diameter. Proposed options for closure of this sizeable defect include the use of biologic grafts to aid in re-epithelialization or creation of a vulvar skin graft [26, 37, 38].

Erosions into adjacent viscera are more challenging to manage. These require surgical intervention and may necessitate coordination and collaboration with urologic or colorectal surgeons. These types of erosion involve removal of mesh segments within the surrounding visceral walls. Rectal erosions can be managed with the use of an anoscope (Figure 164.3). Posterior vaginal mesh may sometimes impinge upon the rectum without eroding through the mucosa, and may lead to defecatory symptoms. In these situations, the mesh may be transected or removed through a transvaginal approach. Close attention is needed to prevent the development of a recto-vaginal fistula (RVF). If an RVF has developed, the mesh in that area should be carefully dissected out and the fistula should be repaired in the usual fashion [26].

Mesh erosion into the bladder may be managed vaginally, cystoscopically, or laparoscopically through a cystotomy. Cystoscopic surgery can be performed with cystoscopic graspers as well as with a 5 mm laparoscopic trocar placed suprapubically into the bladder for placement of laparoscopic graspers and/or scissors. Cystoscopic surgery should be limited to small exposures, such as following a midurethral sling, where suturing is not necessary. Cystoscopy should be repeated a few months later to visualize and document any recurrence of exposure. Benefits of cystoscopic surgery allow for the removal of exposed mesh, and prevention of further damage, without requiring an actual cystotomy. Erosion into the urethra can be managed with a pediatric nasal speculum to allow for circumferential visualization of the mesh fibers. Attempts should be made to avoid cutting into the urethra if possible, as well as avoiding the development of intrinsic sphincter deficiency or a urethrovaginal fistula [26, 39]. If there is concern for ureteral involvement, the placement of ureteral stents may aid in detection of ureteral injury or involvement [15].

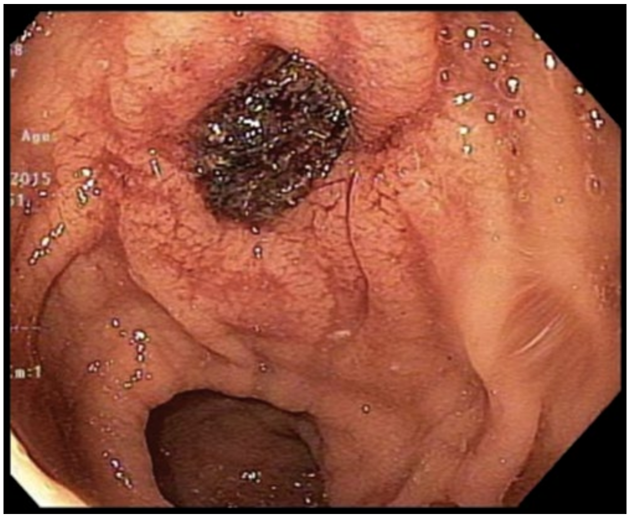

**Figure 164.3** Rectal erosion.

Mesh infection has occurred with and without mesh exposure and the incidence ranges from 0 to 8%. The various bacteria cultured have included Gram-negative and Gram-positive as well as aerobic and anaerobic subtypes. These types of complications were associated with multifilament non-type I meshes, and so have become more rare [18].

For patients with urinary retention from bladder outlet obstruction due to excessive tensioning, midline sling transection should be considered. If left untreated, irreversible scarring of the urethral lumen, voiding dysfunction and bladder remodeling may occur. Patients who present with new-onset urgency complaints should have the sling tension evaluated for possible mesh contraction. The use of 3D ultrasound may be useful in such situations [15].

Dyspareunia or pelvic pain following mesh POP surgery can be difficult to manage. The surgeon should ascertain that the pain is directly related to the implanted mesh, and not due to another condition such as levator spasm, interstitial cystitis, or trigonitis. If there is concurrent vaginal mesh exposure, mesh excision may be helpful. However, in the absence of mesh exposure, patients should be counseled extensively that even with removal of a portion or the entire mesh, their symptoms may not abate and the prolapse may recur [15]. For contracted mesh that leads to palpable focally painful vaginal segments, the mesh arms should be transected as lateral as possible, and the contracted sections should be removed entirely [31].

## Outcomes

Patients must be counseled appropriately before undergoing any surgery or treatment for mesh complications. Patients should be given realistic expectations with regard to possible outcomes, including persistent symptoms, further complications, or worsening of symptoms. Referral of patients to tertiary centers that have experience treating mesh complications should be considered. Outcomes from treatment of mesh-related complications, from conservative therapy to complete mesh removal, can vary tremendously by patient and complication. Success rates have been reported ranging from 25% to 100% for all complications by subjective improvement or cure with varying lengths of follow-up. In addition, several studies report a significant number of patients who have no improvement and a percentage of patients whose symptoms worsened after the second procedure. Of note, excision of mesh for exposure tends to have higher success rates, whereas mesh excision for pelvic pain or dyspareunia is associated with higher persistence rates. With regard to pain, the reported rates of improvement range from 50% to 78%, but persistence of pain is well recognized in the literature. One study, with long-term follow-up of patients who underwent surgical excision of mesh-related complications, 74% of patients reported their pain was improved and 14% reported worsening of symptoms. In that study, it was ascertained that half of the patients reported not being bothered by their residual mesh-related symptoms, whereas just under half reported continued problematic pain. More than half of the patients underwent additional treatments for their complications. Patients with chronic pain disorders (such as fibromyalgia) are three times more likely to have continued (or worsened) pain after mesh implantation and/or removal than those without a chronic pain disorder. However, when pain is associated with mesh erosion or contraction of the mesh, outcomes are much better [15, 19, 31, 40, 41].

## Recommendations for appropriate use

Despite all of the associated complications previously described, vaginal mesh is still an important tool in a pelvic surgeon's armamentarium, and should be considered for certain specific indications. As with any surgery, patients should be counseled extensively regarding the risks of the procedure, all possible alternatives, and their informed consent should be documented in the medical record [3].

Regulatory bodies in Europe and the United States have released recommendations for the use of synthetic mesh for treating POP. Numerous American and international professional societies, including the American College of Obstetricians and Gynecologists, the American Urogynecology Society, and the International Urogynecological Association have released guidelines for patients and healthcare providers regarding TVM for POP repair. They recommend that TVM should be reserved for high-risk patients, in whom the benefits justify the risks. Examples of such patients include those with recurrent POP and large cystoceles, while posterior vaginal compartment prolapse, younger women, primary repairs, and those with underlying pain syndromes likely do not have a demonstrable benefit, and may have a greater risk for complications. The regulations and guidelines are continually changing in this evolving field. It is imperative that physicians are specifically trained in the placement and management of these devices, have a comprehensive understanding of pelvic anatomy, stay current on the research and recommendations, and appropriately counsel patients regarding the risks and benefits of each procedure. A registry should be developed for surveillance of all outcomes [42–45].

## Epidemiology

Prostate cancer is the most prevalent malignancy among men in the United States, and surgical options include open retropubic or robot-assisted laparoscopic radical prostatectomy. Oncologic outcomes are overall favorable, and much attention has been paid to quality of life among men treated surgically for prostate cancer. Urinary incontinence is a significant quality-of-life issue affecting a large proportion of the population [1]. It is estimated that approximately 22.6 million men in the United States are affected by urinary incontinence, and 8.2 million have moderate to severe incontinence [2]. Pure stress urinary incontinence (SUI) accounts for only a subset (12.5%) of these patients, yet it remains a substantial problem. In the era of robot-assisted laparoscopic prostatectomy, the incidence of urinary incontinence at 12 months varies between 4% and 31%. Of these, only 6–9% are bothered enough to elect surgical treatment for their incontinence [3, 4]. In addition, men with prostate cancer who choose radiation therapy, androgen ablation, or even watchful waiting may also develop urinary incontinence with rates of up to 12%, 11%, and 3%, respectively [5, 6].

## Pathophysiology of male continence and post-prostatectomy incontinence

In the male, two sphincteric mechanisms work in concert to provide urinary continence. The proximal sphincter, composed of smooth muscle fibers at the bladder neck extending to the bulbar urethra [7], is under autonomic control; in contrast, the distal sphincter is composed of both striated and smooth muscle fibers extending from the verumontanum to the bulbar urethra [8] and is innervated by both unmyelinated autonomic and myelinated somatic nerves [9]. Magnetic resonance imaging (MRI) and cadaveric dissection studies have demonstrated the length of the distal sphincter to range from 1.4 to 2.4 cm [8, 10, 11]. The smooth muscle fibers of the distal sphincter lie internal to the striated fibers and are contiguous with the smooth muscle fibers of the proximal sphincter [7]. Myers suggested that this rhabdosphincter complex should be thought of as the "sphincteric urethra" (Figures 165.1 and 165.2) [8, 12]. In the physiologically normal male, the intrinsic component of the distal sphincter mechanism is responsible for passive continence, and the extrinsic component of the distal sphincter mechanism is responsible for providing active continence.

Urinary incontinence following surgical prostatectomy may be influenced by a variety of factors, including insufficient sphincteric activity, detrusor overactivity, age, functional urethral length or anatomic abnormalities involving the bladder or vesicourethral anastomosis [13]. In patients who undergo surgical prostatectomy, destruction of the proximal sphincteric mechanism may occur. Many of these patients retain urinary continence solely by action of the distal sphincteric complex. At rest, this is maintained by apposition of urethral tissues. Resting tone is provided by slow-twitch striated fibers, while fast-twitch fibers within the sphincteric complex provide continence during physical exertion or increased intra-abdominal pressure. In response to increases of abdominal or detrusor pressure and during voluntary inhibition of flow in these patients, voluntary activity of the rhabdosphincter fibers may occur in conjunction with associated contraction of levator ani fibers, in order to maintain urinary continence [13, 14]. SUI related to deficiency of

the external sphincteric mechanism is the most frequent type of incontinence following radical prostatectomy. Several studies have demonstrated urodynamic evidence of intrinsic sphincter deficiency (ISD) in the majority of patients with post-prostatectomy incontinence, ranging from 83% to 90% [15–17]. In up to 60% of patients, this may be the only urodynamic finding to account for incontinence [18]. Thus, clinical and urodynamic evidence supports SUI caused by sphincter deficiency as the most common cause of incontinence following radical prostatectomy. It is important, however, to note that transient urodynamic detrusor overactivity may be experienced in 2–77% of men following radical prostatectomy and may persist for up to 1 year [19, 20].

## Management

Active conservative management is often recommended for the first 6–12 months after prostatectomy. In the early postoperative period, reassurance as well as conservative therapy, including pelvic floor muscle strengthening exercises, timed voiding, and avoidance of dietary bladder irritants, may be helpful. Randomized prospective trials have reported quicker return to continence in patients who have undergone pelvic floor strengthening exercises [21, 22]; however, others have reported that this has not been true for patients with severe incontinence and may not extrapolate to long-term continence outcomes [23]. In addition, patient factors including age, comorbidity, preoperative voiding dysfunction, and neurovascular bundle preservation during prostatectomy may influence postoperative return to continence. Unfortunately, pharmacotherapeutic agents for managing male stress incontinence have not been efficacious, nor have they been approved by the US Food and Drug Administration (FDA). Urethral bulking agents may be considered for mild urinary leakage, but success rates are generally low, with fewer than half of patients achieving satisfactory continence [24].

Periodic evaluation of urinary incontinence should be performed at regular follow-up visits during the first year after prostatectomy. Patients with bothersome persistent post-prostatectomy incontinence despite pelvic floor muscle strengthening exercises may be considered for surgery. Contemporary surgical options for post-prostatectomy incontinence include the artificial urinary sphincter (AUS) and the male urethral sling. The AUS was introduced in 1973 [25] and has long been considered the gold standard for the surgical treatment of post-prostatectomy incontinence. The current model, the AMS 800 AUS (American Medical Systems Inc., Minnetonka, MN, USA), has been associated with high success rates (61–96%) [26, 27] and high patient satisfaction in appropriately selected patients [28]. The present chapter focuses on the role of male urethral slings in the treatment of post-prostatectomy incontinence, while more extensive discussion of AUS is provided elsewhere.

## Male urethral sling

The male sling procedure is based upon the theory of passive compression along the ventral urethral surface to maintain continence [29]. The concept of urethral compression by male sling is not new, and before the AUS was introduced, a variety of urethral compression procedures were investigated in an attempt to control urinary incontinence. Most notable were the Kaufman procedures in the 1970s, which included a crural crossover (Kaufman 1) [30], later modified to involve a prosthesis using silicone gel to compress the ventral urethra (Kaufman 2) [31], but it soon fell out of favor. In 1998 Schaeffer et al. described a male sling using three tetrafluoroethylene (Dacron) bolsters beneath the bulbar urethra [32]. A Stamey needle was used to transfer the sutures in the suprapubic area, which were tied across the rectus fascia. Intraoperative resting urethral pressure and abdominal leak point pressures were measured for sling tension. Despite a reasonable short-term success and patient satisfaction [33], this sling was abandoned due to a high rate of complications or reintervention, including bolster removal (6%), sling removal (10%), and severe perineal pain (26%). Since that time, a variety of mechanisms have been employed by which to apply passive external urethral compression with male slings. A primary advantage of using male urethral slings for post-prostatectomy incontinence over the AUS is its minimally invasive nature. They are also less expensive than AUS devices, and unlike the AUS, slings provide fixed urethral resistance and/or repositioning that potentially enables better physiologic voiding [34]. Furthermore, slings avoid the need for manipulating the device and provide an alternative surgical option for patients with mild to moderate incontinence or who refuse to have an AUS.

Recently, Liu et al. [35] evaluated the trend of male sling surgery in relation to AUS in the United States. They reported an overall increased rate of slings from 32.7% in 2004 to 45% in 2013 ($P < 0.001$), with a peak in 2011 when sling placement was 1.6 times more frequently performed than AUS (sling 62.2% vs. AUS 37.8%). There are many types of male slings, including the bone-anchored sling, transobturator sling, and quadratic sling.

### Bone-anchored sling

The InVance™ (American Medical Systems Inc.) bone-anchored male sling (BAMS) represented a major improvement in technique, minimizing invasiveness via a purely perineal approach. With BAMS, a silicone-coated polypropylene sling is secured to the descending pubic rami using 5 mm titanium bone screws. A disposable battery-powered inserter is used to insert a total of six bone screws which are preattached with no. 1 Prolene suture. The silicone-coated mesh is then anchored to the pubic rami, providing the urethral compression. Comiter first reported using BAMS in 2002 [36]. The author reported their experience in patients with both mild to moderate and severe incontinence. They found that patients with mild to moderate incontinence (<5 pads) had a significantly better outcomes compared to those with severe incontinence (>5 pads). Sling failure rates correlated well with the type of material used and the severity of incontinence [37]. Similarly, in a study by Castle et al in 38 patients, none of the patients with severe incontinence were dry after BAMS [38].

Similar results with the InVance BAMS were reported by Rajpurkar et al., who reported overall success rates of 74% and a patient satisfaction of over 70% at a mean follow-up of 24 months [39].

Long-term results with the InVance BAMS were recently reported by Carmel et al. [40]. In their study, 45 patients with post-prostatectomy incontinence underwent InVance sling placement with a median follow-up of 36 months. They underwent regular follow-up at 2, 6, 12 months, and yearly thereafter with pad testing, urodynamics, history, and UCLA/RAND and American Urological Association (AUA) symptom score data. Thirty-six percent of patients were dry, 40% improved, and 24% reported failure. The vast majority of patients (86%) considered themselves cured or almost cured, and 72% were satisfied or very satisfied with the procedure. Complications included temporary perineal numbness lasting 1–3 months in 22%, temporary urinary retention in 7%, overactive bladder in 4%, and mesh infection necessitating removal in one patient.

Similarly, a recent French multicenter study described treatment success and predictors of failure among 84 patients treated for incontinence with InVance male slings [41]. In this study, at a mean of 20 months, 45% of patients were dry, 26% improved, and 29% had treatment failure. Univariate analysis identified three features as predictors of treatment failure: severe urinary incontinence, urodynamic instability, and a history of bimodal therapy for prostate cancer including radiation therapy. Failure rate was 67% if two or more of these factors were present versus 25% if one or none was present ($P = 0.013$). Bimodal therapy was the sole independent predictor of failure in multivariate analysis in this study [41].

In our 5-year experience with BAMS in 87 patients published in 2007, we found that only 52.8% of patients were cured and another 25.2% significantly improved of their incontinence, while 21.8% failed the sling procedure [42].

Fischer et al. used a risk analysis model to predict success in 62 men treated for post-prostatectomy incontinence with BAMS and found that among several factors (time from prostatectomy, age, abdominal leak point pressure, pad weight testing, maximum bladder capacity, detrusor overactivity, International Prostate Symptom Score (IPSS), and Urinary Distress Inventory (UDI-6)), only preoperative pad weight of less than 423 g/day was a predictor of success. Patients with less than 423 g/day leakage had a 71% chance of success and were six times more likely to have success as defined by perception of very much or much better on Patient Global Impression of Improvement (PGI-I) questionnaires [43].

Complications reported with BAMS included transient retention in 2%, overactive bladder in 5%, mesh erosion in 2%, infection in 2%, and perineal pain in 15% [44].

Because of the potential risk of bone infection and bone pain from the bone screws, this male sling has been removed from the market and is no longer available for implantation.

## Transobturator sling

Whereas BAMS function by fixed urethral compression, transobturator slings were subsequently developed based on the concept of proximal relocation of the sphincteric urethra. Rehder and Gozzi described a novel technique for placement of a polypropylene tape beneath the bulbar urethra using the transobturator approach in a series of four cadaveric and 20 human male patients [45]. The middle part of the tape was fixed distally to the bulb and proximally to the perineal body, and when tension was applied to the ends of the tape, the proximal anterior urethra was relocated proximally by a distance of 3–4 cm, effectively lengthening the membranous urethra. Baseline and postoperative video urodynamics in their clinical series confirmed that at rest, the bladder neck and posterior urethra were more occluded, and the bladder neck was closed and more elevated than at baseline. In addition, postoperative video urodynamics demonstrated a more elongated membranous urethra during micturition, having increased from a mean of 3 mm to a mean of 17 mm following placement of the tape. Urethral pressure profilometry in the same series demonstrated an improvement of supine mean urethral closing pressure at rest from 13.2 cmH$_2$O preoperatively to 86.4 cmH$_2$O postoperatively.

The rationale for treating post-prostatectomy male incontinence by transobturator tape is based on the theory that post-prostatectomy men with partially intact external sphincteric complexes may develop incontinence due to urethral hypermobility, resulting in urethral subluxation or perineal descent from the pelvis, possibly associated with coexistent levator laxity; hence proximal relocation of the sphincteric urethra may result in improved continence [45, 46].

Gozzi et al. reported continence results among 67 post-prostatectomy patients treated with transobturator urethral slings [47]. At three months postoperatively, 52% were cured (no pads) and 38% had improvement of incontinence (1–2 pads/day). Complications included persistent incontinence requiring sling replacement in five patients (7%), suprapubic drainage for postoperative retention in 11 patients (16%), and subsequent placement of AUS in two patients (3%). A recent prospective multicenter trial by Cornel et al. examined pad weight test results at three months and 1 year following AdVance™ (American Medical Systems Inc.) transobturator sling suspension in 37 men with incontinence following radical retropubic prostatectomy (RRP) and transurethral resection of the prostate (TURP) [48]. The overall cure rate was 14.3% at three months and 9% at 1 year. Improvement was noted in 42.8% at three months and 36.5% at 1 year. Pad testing demonstrated worsening incontinence in 14.2% of patients postoperatively. In addition, urinary bother recorded by the visual analog scale (VAS) was improved at three months postoperatively, but was not significantly different at 1 year. VAS score correlated with objective cure or improvement on pad weight testing. Interestingly, cure as defined by pad weight testing occurred only in the RRP group, with no patients cured who had TURP or radiotherapy in addition to RRP. Preoperative incontinence using pad weight cutoffs of 200 and 400 ml/day, or fewer or greater than 5 pads/day, was not significantly associated with pad testing or VAS improvement. The results in the report by Cornel et al. [48] are less favorable than in those by Gozzi et al.'s series [47]. The reason for the discrepancy between the series is unclear, but Cornel et al.'s study does suggest that patients who have had TURP or radiotherapy may not benefit from transobturator sling placement based on the definitions used for successful outcome in their study. In addition, it is important to note that when compared to continence results with

AUS, outcomes reports with male slings have been widely variable and difficult to interpret owing to small, single-center studies with short follow-up periods and variable definitions of success.

Recently, Rehder et al. [49] reported outcomes at 3 years with 53% cured, 23.8% improved, and 23% failed after sling. There was higher success in mild to moderate incontinence as compared to severe incontinence. Clinical outcomes were also compared in "ideal" versus "non-ideal" patients by Sturm et al. [50]. Six patient selection criteria were established:

- Less than four pads/day or <300 g daily pad weight
- Intact-appearing external urinary sphincter on cystoscopy
- No history of pelvic radiation
- No history of previous surgical procedure to treat incontinence
- Volitional detrusor contraction when voiding
- Postvoid residual urine volume <100 ml.

It was noted that there was significant reduction in both pad usage (77% vs. 46%) in patients who met all six criteria when compared to patients did not meet all criteria. Similarly, pad weight reduction was significantly lower in the group who met all six criteria (88% vs. 61%) when compared with the group who did not meet all criteria.

A new modified transobturator sling (AdVance® XP, American Medical Systems Inc.) has been introduced recently by the same manufacturer. It obtained FDA approval in Canada in 2011 but has not yet been approved in United States. The enhancements include new mesh design, longer arms, Tyvek sleeve liner, and Chevron anchoring mechanism to increase the holding power and consistent displacement of load.

Available data in the literature comparing AdVance XP to conventional AdVance slings showed similar cure rates of 63% versus 59% in Advance and Advance XP slings, respectively. Similarly, 16% in the AdVance group and 17% in the AdVance XP group improved significantly. Failure rates were comparable (21% for AdVance versus 24% for AdVance XP) [51].

In another recent long-term prospective trial by Kretschmer et al. comparing AdVance and AdVance XP slings [52], higher cure rates were reported in the AdVance XP group (64.3% vs. 46.2%), while higher failure rates were reported in the AdVance group (30.8% vs. 7.1%).

Surgical treatment of male stress incontinence with urethral slings raises the question of *de novo* obstruction or associated urodynamic changes. This question was evaluated by Davies et al., who performed baseline and three-month postoperative urodynamic testing on 13 patients undergoing placement of AdVance male urethral slings for post-prostatectomy incontinence. At three months postoperatively, Valsalva leak point pressure (VLPP) significantly improved from 29.3 to 46.6 $cmH_2O$ ($P = 0.03$), but there was no difference in baseline and postoperative detrusor voiding pressure, maximum or average flow rates, or postvoid residual volume [53].

### Quadratic sling

The newest addition to the repertoire of male slings is the quadratic sling from Coloplast Corporation (Minneapolis, MN, USA). It is designed to provide a broad area of urethral compression *and* to achieve proximal relocation of the membranous urethra. Quadratic fixation is achieved with both transobturator (TO) and prepubic (PP) components. The Virtue® sling is a synthetic, monofilament polypropylene knitted mesh that measures 5.5 cm × 7 cm, with 1.5 cm × 25 cm superior extensions and 1.5 cm × 22.5 cm inferior extensions.

By combining the mechanisms of action of the bone-anchored and transobturator retroluminal slings, the quadratic device can increase urethral resistance more than a purely perineal or TO approach. This was confirmed in a cohort of 22 men with post-prostatectomy incontinence undergoing Virtue sling placement. The mean urethral resistance increased from a baseline retrograde leak point pressure (RLPP) of $33.4 \pm 8.8$ $cmH_2O$ to a mean post-tension RLPP of $68.8 \pm 6.0$ $cmH_2O$ [54].

Another multicenter trial involving 31 incontinent men managed with quadratic sling was recently reported by Comiter et al. [55]. The cohort included 43.3% patients with mild, 23.3% with moderate, and 33.3% with severe incontinence. Median percent reduction in pad weight for the cohort was 89.3% at 6 weeks and 88.3% at 12 months. This did not differ significantly among the subgroups based on baseline pad weight. For those with mild leakage, percent reduction in pad weight at 12 months was 89.7%, 89.6%, and 72.2% in the mild, moderate, and severe groups, respectively.

Complications reported were mild overall and included mild genital paresthesias (19.4%) and mild perineal pain (12.9%). There were no instances of infection or erosion. It was also noted that the success rate was no different in the 19% of patients who underwent adjuvant radiation compared to those who did not. This is in contrast to other male slings, which traditionally have poorer outcomes in patients who have undergone radiation.

## Patient selection and evaluation

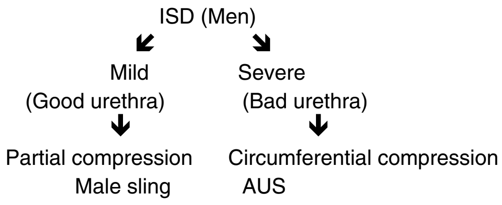
Careful evaluation and patient selection is important when pursuing slings to treat male urinary incontinence. Ideally candidates should be at least 6–12 months post-prostatectomy and exhibit mild-to-moderate incontinence.

Features that might be predictive of failure should be considered, including high-volume incontinence, comorbidity status, and mixed or urge-predominant incontinence. Caution should be exercised when considering slings in patients who have undergone radiation therapy. History of prior incontinence procedures, patient age, manual dexterity, and patients' preferences should also be taken into account. Careful history-taking is paramount. Physical examination, for example with a standing cough test, should be performed for documentation and gross quantification of stress incontinence. Cystoscopy should be performed on all candidates to confirm the presence of some sphincteric coaptation and to rule out urethral stricture or bladder neck contracture. When history suggests mixed incontinence with urgency or if neurologic disease coexists, urodynamics evaluation should be considered to evaluate detrusor activity. As with all interventions for incontinence, caution should be used when patients have detrusor overactivity.

Detrusor hypocontractility is a contraindication for sling placement, whereas an AUS may still be appropriate in this setting. In addition, patients who have previously undergone incontinence surgery with either a sling or AUS may be more likely to benefit from AUS than a repeat sling [56]. Patients with risk factors for sling failure, including severe stress incontinence or history of radiation therapy, may be better served by AUS than a sling. Despite these risk factors, however, male slings may be indicated in otherwise appropriately selected patients with poor dexterity to operate an AUS.

Kumar et al., interestingly, found that when faced with a choice of AUS versus male sling, 25% of patients preferred to have a sling in spite of their urologist's recommendation to pursue AUS instead [57]. Furthermore, when given a choice, 92% of patients chose sling over AUS. The primary reason for these findings appears to be the desire of many patients to avoid a mechanical device that would require manipulation.

We propose the following surgical treatment algorithm to stratify patients based on their degree of ISD:



In the absence of risk factors for sling failure, many patients may benefit from either a sling or AUS and should understand the merits of each in the process of making an informed decision. It is also important for patients undergoing incontinence procedures to have realistic expectations concerning outcomes.

## Surgical technique

Placement of bone-anchored slings is described, but emphasis is given to the placement of the more commonly used transobturator male slings.

### InVance bone-anchored slings

The patient is positioned in the high dorsal lithotomy position under general anesthesia with the perineum prepped and draped. A 14 Fr urethral catheter is placed for bladder drainage and urethral identification during the procedure. A 4 cm midline perineal incision is made over the urethra after palpating the catheter and ischial tuberosities. Dissection is carried down over the urethra, leaving the bulbospongiosus muscle intact. Dissection is directed laterally to the pubic tubercle, and descending pubic rami are identified. The inferior aspects of the pubic rami are identified. A Scott/Wilson or similar retractor is placed into the incision for exposure. The applicator is used to insert six 5 mm titanium screws as bone anchors into the pubic rami. Three bone anchors are placed 1 cm apart into each descending ramus, just inferior to the pubic symphysis. The most inferior bone anchor should be placed no more inferiorly on the descending ramus than at the level of the bulbar urethra. Each bone anchor is preattached to a no. 1 Prolene suture. An audible change in pitch indicates that the anchor has been inserted to the appropriate depth. The sling is a 4 × 7 cm sheet of pliable mesh composed of silicone-coated multifilament polyester known as InteMesh. The mesh may be trimmed to fit the patient in some cases. One side of the mesh is first tied down snugly with the Prolene sutures attached to the bone anchors in one pubic ramus. Sutures should be placed at least 1 cm medially from the edge of the mesh to provide optimal strength. The second side of the mesh is similarly tied down tightly using the Prolene sutures attached to bone anchors on the second pubic ramus. The mesh should be tied down as tightly as possible to provide maximum tension. An alternative involves intraoperative leak point determination to determine the appropriate mesh tension prior to tying down the second side of the mesh. The perineal incision is closed in three layers using two layers of 3-0 Vicryl and skin with 4-0 chromic suture to complete the procedure.

### AdVance transobturator slings

The patient is positioned in high dorsal lithotomy position under general anesthesia. The anal area is covered and isolated from the surgical field by using a sterile towel. A 14 Fr urethral catheter is placed for bladder drainage and urethral identification. A midline perineal incision is made (Figure 165.3) and carried down to the

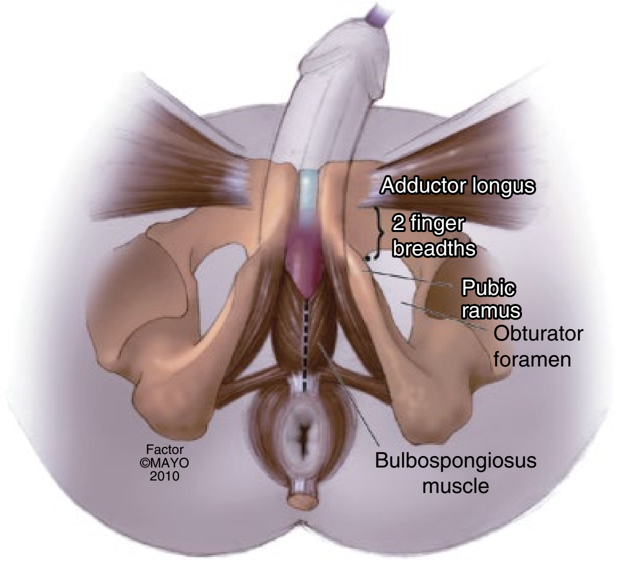


**Figure 165.3** Relevant pelvic anatomy for placement of a transobturator male sling. A midline perineal incision is made. Bilateral stab incisions are made two fingerbreadths posterior to the adductor longus tendon at the level of the base of the penis. *Source:* Dr. Ajay Nehra. Reproduced with permission of Dr. Ajay Nehra.

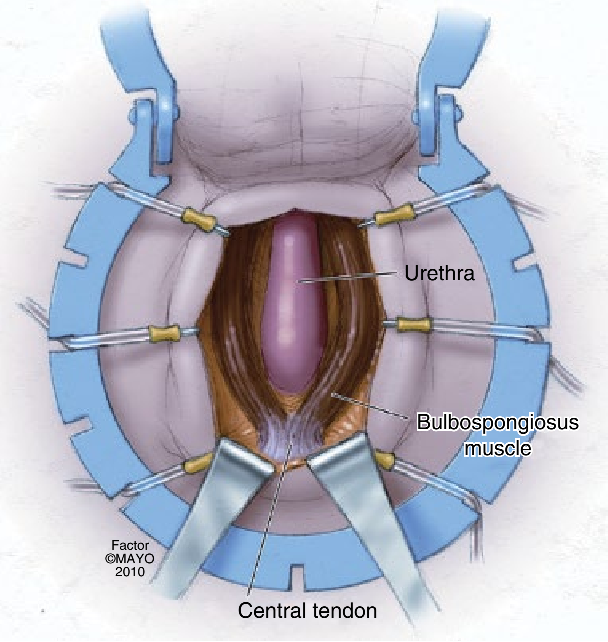

**Figure 165.4** Urethra is identified within the midline perineal incision. The bulbospongiosus muscle is spared. A self-retaining retractor is placed into the incision for exposure. *Source:* Dr. Ajay Nehra. Reproduced with permission of Dr. Ajay Nehra.

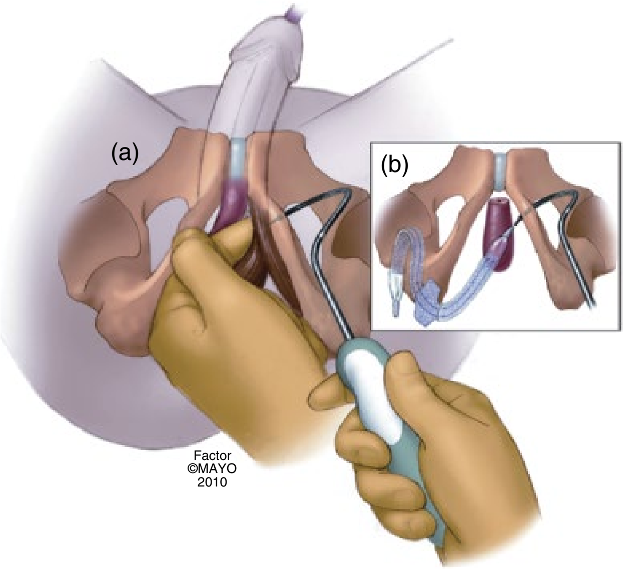

**Figure 165.5** (a) A curved trocar is placed through the stab incision. The descending pubic ramus is encountered and the trocar then angled laterally and passed through the obturator ring with index finger guidance. The trocar follows the index finger into the perineal incision. This process is then repeated on the contralateral side. (b) Each end of the AdVance sling is then attached to a trocar eye and brought out through the stab incision. *Source:* Dr. Ajay Nehra. Reproduced with permission of Dr. Ajay Nehra.

bulbar urethra, which is identified by palpation of the catheter. The bulbospongiosus muscle is left intact (Figure 165.4). A self-retaining Scott/Wilson retractor is placed into the incision for exposure. The perineal body is only partially dissected during mobilization of the bulbar urethra. Two separate stab incisions are made bilaterally 1 cm inferior to the adductor longus tendon, in the groin area. An introducing trocar is passed through one of the stab incisions using an outside-to-inside approach. The tough obturator membrane is then perforated with the trocar, which is advanced medially and passed through the obturator membrane and ring. An index finger is used through the perineal incision to guide the trocar out through the perineal incision. This finger also protects the urethra simultaneously from any inadvertent injury. A second trocar is then passed through the contralateral stab incision in the same manner. The distal ends of the sling are passed through the eye of each trocar and brought out with each trocar through the stab incisions (Figure 165.5). The mesh at the center of the sling is placed flatly against the sphincteric urethra. Cystoscopy is performed to exclude urethral or bladder injury. Tension on the sling is adjusted under direct vision using urethroscopy so that acoaptation is noted at the sphincteric urethra without obstruction of the lumen (Figure 165.6). The mesh is then fixed to the bulbospongiosus muscle overlying the bulbar urethra using one 3-0 Vicryl suture at each corner. Sleeves are removed from the ends of the mesh and, using a right angle, the distal ends of the sling and attached suture are tunneled out of separate stab incisions approximately 2 cm inferomedial to the initial stab incisions bilaterally. Sleeves are removed from the arms of the sling, and the excess mesh is excised (Figure 165.7). Stab incisions are closed with simple 4-0 Vicryl suture. The perineal incision is then closed using two layers of 3-0 Vicryl and skin using 4-0 chromic suture (Figure 165.8). Oral antibiotics are prescribed for one week, and strict activity restrictions are implemented, including no hard chairs, biking, sexual activity, or lifting more than 5 kg for 2–3 months.

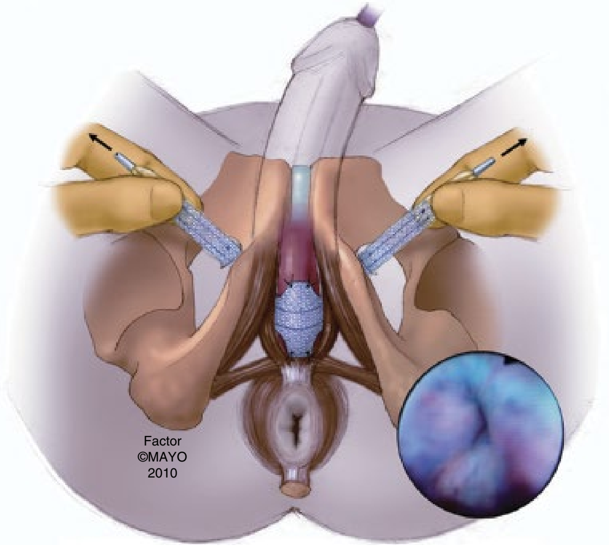

**Figure 165.6** Mesh is placed flatly against the urethra and anchored in four corners with 3-0 Vicryl suture. Urethroscopy is performed, and tension is applied to the ends of the mesh under urethroscopic vision to confirm appropriate coaptation of the sphincteric urethra. *Source:* Dr Ajay Nehra. ## Coloplast Virtue male sling

The Coloplast Virtue sling involves mesh that employs two prepubic arms and two transobturator arms in order to provide quadratic fixation of the bulbar urethra (Figure 165.9). This system is designed to provide both urethral elevation and compression, combining properties of both bone-anchored and transobturator slings in order to improve post-prostatectomy continence.

The patient is positioned in dorsal lithotomy under general anesthesia. The anal area is covered and isolated from the surgical field by using a sterile towel. A 14 Fr catheter is placed to help identify the urethra, and a vertical midline perineal incision is made and carried down to the bulbar urethra. A self-retaining Scott/Wilson retractor is used for adequate exposure. The urethra and descending pubic rami are exposed bilaterally, while leaving the bulbospongiosus muscle intact. Using sharp dissection, the bulbous urethra is partially detached from the central tendon to the perineal body, thereby allowing mobility of the bulbar urethra. Two separate stab incisions are made bilaterally 1 cm inferior to the adductor longus tendon, in the groin area.

For the TO arms of the sling, the semilunar trocars are passed in an inside-to-out fashion, from the perineal incision out through groin stab incisions. The urethra is protected while passing the trocar. The obturator membrane is encountered as a tough structure and is perforated with the tip of the trocar. The trocar tip should exit from groin approximately 1 cm inferior to the insertion of the adductor longus tendon, which is easily palpable. The suture attached with the TO arm of the sling is looped into the eye of the trocar. Skin overlying the trocar tip is incised, and both the tip of the trocar and the attached suture are exposed. The arm of the sling and the attached suture are pulled out through the groin incision.

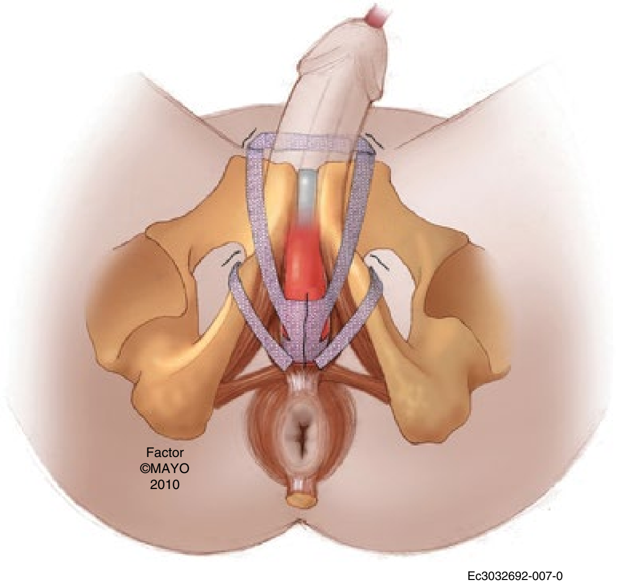

**Figure 165.9** Coloplast Virtue male sling. *Source:* Dr. Ajay Nehra. Reproduced with permission of Dr. Ajay Nehra.

Next, attention is diverted to the prepubic area to place the prepubic arms. The semilunar trocar for the prepubic arms of the Virtue sling is passed in an out-to-in fashion in the subcutaneous tissue plane anterior to the pubic bone. Two stab skin incisions are made 2–3 fingerbreadths lateral to midline overlying the pubic symphysis. The semilunar trocar is then passed from the pubic incision, anterior to the pubic bone out through the perineal incision guided with the index finger of the contralateral hand. The perineal incision may be retracted cephalad to assist with the trocar passage. The suture loops from the prepubic arms are then attached to the ends of the semilunar trocar, and the prepubic extensions of the sling are transferred through the pubic incision. Sling arms are then progressively and symmetrically tensioned such that the transobturator arms elevate the bulbar urethra by 2–3 cm, and the prepubic arms provide compression of the bulbar urethra. The mesh is laid flat in this fashion opposite the bulbar urethra. Next the Foley catheter is removed. To confirm appropriate sling tension, an RLPP is obtained by inserting a small catheter into the fossa navicularis and then connecting this to a saline bag with the drip chamber set at a water height of 60 cm above the pubic symphysis. For sling tension, the saline is allowed to flow, and progressive sling tension is applied to the transobturator arms until the drip chamber flow starts to slow. Next progressive tension is then applied to the prepubic arms until the drip chamber flow completely stops. This indicates that urethral pressure of 60 $cmH_2O$ has been achieved.

Once the appropriate sling tension has been achieved, the distal aspect of the sling adjacent to the prepubic arms is secured to the underlying periosteum using a 2-0 Prolene suture. The TO arms are then tunneled subcutaneously back through the perineal incision using a hemostat, and then the overlapping transobturator arms are fixed to each other in the midline using 2-0 Prolene suture. The excess sling arms are transected below the skin level. Likewise, for the prepubic arms, once properly fixated, the plastic sleeves of the prepubic arms are removed and the arms trimmed below the skin level. Incisions are then irrigated with antibiotic solution. The stab wounds and the perineal wound are closed in multiple layers. A 14 Fr catheter should be left in overnight, followed by a trial of voiding on postoperative day 1. Patients are advised to avoid lifting objects heavier than 5 kg for at least six weeks following surgery. They should also refrain from strenuous activity that might place excess stress on the perineum, including running, squatting, bicycle riding, and sexual activity.

## Conclusions

Advances in the diagnosis, management, and treatment of men with SUI have resulted in various surgical options. A meticulous preoperative evaluation and long-term analysis of outcomes and results will provide insights into success following sling surgery. Male sling surgery has emerged as a safe and efficacious alternative to AUS placement in properly selected men with post-prostatectomy incontinence. Slings are preferred by most patients over the AUS, as the need to manipulate a scrotal pump to permit bladder evacuation can be avoided. Patient selection remains the key to success in any male sling surgery. In particular, in patients with mild to moderate SUI with normal bladder contractility, intermediate-term results with sling surgery appear equivalent to those for AUS placement. Similarly, patients with history of prior radiation and/or prior incontinence procedures should not be offered male sling. There are limited data available for the newer quadratic slings, and long-term data are presently lacking for male slings. Patients should be counseled appropriately and provided with realistic expectations.

## Introduction

Chronic urinary frequency, urgency, and urge incontinence, collectively referred to as overactive bladder (OAB), are a common cause of voiding dysfunction and a frequently seen problem in the urologist's practice. Approximately 30 million people in the United States have OAB, leading to significant impairment in quality of life, a higher risk of falls, lower self-esteem and health perception [1]. Annual cost associated with OAB, including direct care, health consequences, and lost productivity, is estimated at more than US$10 billion [2].

For patients with OAB, first-line treatment options include conservative therapies, such as behavioral interventions, pelvic floor exercises, and biofeedback, followed by pharmacologic therapy. Although many patients find relief with these therapies, up to 40% of patients are either refractory to primary management or have an unsatisfactory response [3], and other options must be considered. Currently, several options exist for these patients, ranging from intradetrusor injection of botulinum toxin to irreversible surgical therapy, including detrusor myomectomy, augmentation cystoplasty, and urinary diversion. Unfortunately, these procedures are also associated with significant morbidity. Bladder botulinum toxin injection recently received US Food and Drug Administration (FDA) approval for use in patients with neurogenic and idiopathic OAB. Although results have been promising, there is a need for repeat injections and data on long-term results are lacking. Sacral nerve stimulation (SNS) as well as percutaneous tibial nerve stimulation (PTNS) offer attractive alternatives which are state-of-the-art, minimally invasive, and reversible treatments with a high rate of success for patients with voiding dysfunction (urinary retention or OAB) for whom conservative therapies have failed prior to consideration of more invasive and irreversible treatment modalities.

In this chapter we review the history of these novel techniques, as well as the current state of electric neuromodulation (sacral and tibial) for the treatment of refractory voiding dysfunction, including a detailed description of the therapies, possible mechanisms of action, indications for the procedures, patient selection, surgical techniques, efficacy/outcomes, risks/benefits, and cost considerations.

## Historical perspective

Neuromodulation therapy for voiding dysfunction and urinary incontinence represents a recent step in the long history of the use of electrical stimulation for medical purposes. Caldwell [4] reported (in 1963) the use of electrical stimulation of the pelvic floor by implanted electrodes to control stress urinary incontinence and attempted to treat neurogenic incontinence with an implantable stimulator. The instruments in that era were rudimentary; however, with advances in cardiac pacing and improved understanding and miniaturization of electronic instruments, interest in neuromodulation of bladder function was revived in the 1970s and 1980s. Most of the credit for laying the foundation of neuromodulation as it is performed today goes to Drs. Schmidt and Tanagho [5, 6] who did many of the early studies at the University of California, San Francisco. Their work was instrumental in advancing the use of SNS for the treatment of refractory voiding dysfunction. They demonstrated that by using an electrode connected to an implanted pulse generator to provide continuous stimulation of sacral root S3, detrusor and sphincter activity

*Smith's Textbook of Endourology*, Fourth Edition. Edited by Arthur D. Smith, Glenn M. Preminger, Louis R. Kavoussi, and Gopal H. Badlani.
© 2019 John Wiley & Sons Ltd. Published 2019 by John Wiley & Sons Ltd.
Companion website: www.wiley.com/go/smith/textbookofendourology

could be modulated and micturition reflexes stabilized. Further research in understanding the mechanism of neuromodulation was done by Drs. Craggs and Fowler in London and Drs. de Groat and Chancellor at the University of Pittsburgh in the mid-1990s [7, 8].

Initially, SNS was performed as a two-stage procedure, and the quadripolar lead electrode was placed through an open sacral incision; the implantable pulse generator (IPG) was placed in the abdomen. The procedure was relatively involved and took approximately 2 hours to perform. The first major change was placement of the IPG in the upper buttock region. This helped decrease both the time needed to perform the procedure and the rate of infection. The next major change was the development of the tined lead, allowing percutaneous lead placement under fluoroscopy. This change made the procedure less invasive and further decreased the time needed to perform it.

The initial large-scale trials were performed in the mid-1990s when Medtronic Incorporated bought the technology from a struggling startup company and completed FDA trials, leading to the approval of SNS for the treatment of urge incontinence in 1997 and for frequency/urgency as well as nonobstructive urinary retention in 1999. Since then, SNS has been used successfully in over 26 000 patients for lower urinary tract dysfunction [9].

## Mechanism of action

The mechanism of action of neuromodulation on voiding dysfunction has not been fully elucidated. In general, neuromodulation works on the principle that activity in one neural pathway can influence activity in another neural pathway. The S2–S4 nerve roots provide the primary autonomic and somatic innervation to the bladder, urethra, and pelvic floor. It is known that contractions of the pelvic floor and voluntary external sphincter can abolish unstable bladder contractions. This may represent one of the mechanisms whereby stimulation of the S3 or S4 nerve root results in strengthening of the pelvic floor and sphincter, resulting in a more appropriate relaxation of the pelvic floor and urethra with less bladder instability.

Chancellor and de Groat [10, 11] have suggested SNS improves somatic afferent inhibition of sensory processing in the spinal cord, playing an important role in modulating abnormal micturition. Schmidt et al. [12] noticed significant improvement in voiding dysfunction through the strengthening of the pelvic floor and external sphincter through efferent-mediated augmentation of the guarding reflex. Fowler and colleagues [8] suggested that neuromodulation affects afferent pathways through changes in the spino-bulbospinal pathways to the pontine micturition center. Gronewald et al. [13] have noted that the beneficial effect of SNS can occur without efferent activation of muscle fibers. It is likely that both efferent and afferent mechanisms play a role, with patients primarily with frequency and urgency helped more through afferent sensory mechanisms, and those with primarily urge incontinence improving as a result of increased efferent activity.

Chronic SNS has been shown to lead to augmented somatosensory cortical responses to evoked potentials along the pudendal and posterior tibial nerves [14]. Furthermore, through positron emission tomography studies, additional neural plasticity is observed over the course of neuromodulation in cortical areas associated with motor learning and with pelvic floor and abdominal musculature [15]. Suffice it to say that modulation of the sacral nerve toots restores a more normal relationship between the excitatory and inhibitory urinary control systems, helping the two extremes of voiding dysfunction/urinary retention and urge incontinence.

## Indications and efficacy of sacral neuromodulation

All patients considered for SNS should have a complete history and physical examination, including a genital, rectal, and neurological examination. These patients should perform accurate voiding diaries and generally undergo urodynamic studies to confirm the diagnosis and ascertain whether they are suitable candidates.

### Overactive bladder

The first American Urological Association (AUA) guidelines on OAB released in 2009 focused on 13 studies in the literature of largely single-group observational designs, which evaluated the efficacy and adverse events of SNS in patients with severe refractory OAB symptoms, many of whom had failed multiple other therapies. Greater than 50% improvement was observed at 5 years in 68% of patients with urgency incontinence and in 56% of those with frequency urgency in those who initially had success with the external testing and went on to pulse generator implantation [16].

The updated literature review, and most recently updated AUA guidelines on OAB (May 2014) examined an additional 16 relevant treatment studies, including one prospective randomized multicenter trial, one crossover study, and another 14 observational studies. These recent studies corroborated similar efficacy reported in the prior guidelines [17]. The guidelines concluded that clinicians may offer sacral neurostimulation (SNS) as *third-line* treatment in a carefully selected patient population characterized by severe refractory OAB symptoms or patients who are not candidates for second-line therapy and are willing to undergo a surgical procedure. Given its lower side-effect profile, some experts argue that SNS should be offered as first-line therapy for OAB in the elderly, who may experience significant mental status changes with anticholinergic therapy.

## Nonobstructive urinary retention

Prior to the introduction of neuromodulation many of the patients with this disease entity were managed with intermittent catheterization and/or indwelling catheter, given that no pharmacologic therapy was found to be sufficiently efficacious to treat these patients. Recent studies have shown that a significant number of patients with nonobstructive urinary retention who have undergone SNS treatment have been able to eliminate catheterization in six months (50–69%) as well as decrease catheterization volumes (PVR) (70–80%) [18–20]. SNS has even been shown to be particularly efficacious in patients with Fowler's syndrome (young women with idiopathic retention and specific EMG findings) [21].

## Expanding indications

Since the introduction of SNS for OAB and nonobstructive urinary retention, there has been growing recognition of the potential benefit of SNS for a broader range of pelvic disorders that may involve some OAB symptoms. Although some these applications are investigational and represent off-label use, research is ongoing into the potential use of SNS for interstitial cystitis/painful bladder syndrome (IC/PBS)/pelvic pain, neurogenic voiding dysfunction, and sexual dysfunction. Early evidence suggests that some patients with these conditions may also benefit from sacral neuromodulation, potentially further expanding the indications for SNS.

## Interstitial cystitis/painful bladder syndrome

Urinary symptoms in patients with IC/PBS may respond better to SNS than do pain symptoms. Multiple small series have demonstrated at least significant short-term efficacy [22, 23]. The highest response rates were reported by Comiter [22] for carefully selected patients who underwent a successful period of test stimulation. In this study, only 27 of 39 patients progressed from test stimulation to permanent implantation, but the rate of success was 94% among those patients undergoing permanent implantation. Given the increasing evidence of the efficacy of sacral neuromodulation in patients with IC/PBS this treatment is currently considered part of the AUA and European Association of Urology (EAU) guidelines for the management of IC/PBS [24, 25].

## Fecal incontinence

The FDA recently approved sacral neuromodulation for the treatment of refractory fecal incontinence. Several prospective studies have reported on the efficacy of SNS for the treatment of refractory fecal incontinence with or without sphincter defects [26, 27]. Wexner et al. [27] reported on outcomes of a large prospective cohort of 120 women with refractory fecal incontinence and showed a significant reduction in incontinence episodes from nine episodes at baseline to two episodes at 1 year. They also reported significant clinical improvements in Fecal Incontinence Severity Index scores, Fecal Incontinence Quality of Life Questionnaire, use of pads and other forms of protection, and overall self-perception of bowel health.

## Neurogenic bladder

Lombardi and Del Popolo [28] studied the efficacy and safety of SNS in patients with incomplete spinal cord injury suffering from neurogenic lower urinary tract symptoms with a mean follow-up of 61 months. Those patients with urinary retention reported a 50% improvement in baseline voiding parameters, with a significant decrease in the number of catheterizations and a significant increase in the frequency of voids and voided volume. Furthermore, at the conclusion of the study, 38% of patients no longer required catheterization for bladder emptying. A major practical limitation of SNS for neurologic disorders (spinal cord injury and multiple sclerosis patients) is the need of many of these patients to undergo magnetic resonance imaging (MRI) studies. MRIs have been shown to cause heating of the leads, and may damage the IPG [29, 30]. It is contraindicated to perform a MRI in a patient who has undergone SNS with an IPG, with the exception of brain MRI. As such, it is important that the patient's neurologist be informed and be part of the decision-making process prior to performing SNS.

## Sexual dysfunction

Improvement in female sexual function after SNS treatment has been suggested in recent studies in the literature in a subset of patients suffering from idiopathic and neurogenic detrusor overactivity. Statistically significant improvement has been noted in terms of desire, lubrication, orgasm, satisfaction, and pain [31]. Furthermore, studies have also reported improvement in Female Sexual Function Index (FSFI) and Female Sexual Distress (FSDS) scores [32, 33]. It is hypothesized that the mechanism of action of SNS on improvement of sexual dysfunction relies on pudendal nerve integrity [31]. However, this remains a debated topic in the literature, and large multicenter prospective controlled trials are needed to provide good-quality results and demonstrate a possible direct effect of SNS and improvement in sexual dysfunction.

## Sacral neuromodulation test procedure

A test procedure provides a short-term trial of 3–7 days of SNS and is important to patient selection before permanent implantation of an IPG. This is sometimes referred to as percutaneous nerve evaluation (PNE). It lets the patient and physician decide whether the benefits of permanent IPG implantation are worthwhile while weighing the benefits, risks, and costs of the therapy. The test procedure can be performed in the office under straight local anesthesia using fluoroscopy guidance; alternatively, a test procedure using permanent tined leads can be performed in the ambulatory surgery unit or operating room. The patient should complete a 2- to 3-day voiding diary before the test procedure.

### Percutaneous nerve evaluation

The patient is placed in the prone position with one or two pillows under the lower abdomen to improve the sacral approach. The sacrum, buttocks, and perineum are sterilely prepped with antiseptic solution and the sterile drapes are placed to allow for visualization of the buttocks and gluteal crease, as well as the patient's feet and toes, during the procedure (Figure 166.1). The sacral notches and coccygeal drop-off are identified by palpation or fluoroscopy. S3 usually is located 1.5–2 cm lateral to the midline at the level of the sacral notches, or about 9 cm above the coccygeal drop-off. Local anesthesia is achieved from S2 to S4 over the underlying skin and subcutaneous tissue, making certain not to enter the foramen. Insulated foramen needles are inserted percutaneously into the foramen at a 60° angle relative to the skin in the S3 and S4 foramens, using the previously mentioned landmarks and fluoroscopic guidance (with primarily lateral imaging). The test stimulator is connected to the foramen needle via the test stimulation cable, and stimulation is applied (Figure 166.2).

With electrical stimulation applied, the clinician observes for appropriate sensory and motor responses to stimulation. If the appropriate responses are not observed, the needle may be adjusted up and down to change the depth, or a second foramen needle may be placed on the contralateral side. If the sensory and motor responses are inconsistent with sacral nerve S3 response, then the needle must be reinserted into a different foramen and retested. If the desired responses are seen, the temporary test stimulation lead (wire) is inserted into the foramen needle until the lead electrode exits the needle tip (determined by markings on the lead). The lead is retested for appropriate responses, and if confirmed, the foramen needle is removed over the lead, leaving the lead in place in the S3 foramen. The patient can try out left and right sides or S3 and S4 and decide on the best response. Sacral radiographs are used to document the position of the wire electrode immediately after the procedure (Figure 166.3). Once the wires are attached to an external stimulator and secured the patient is sent home.

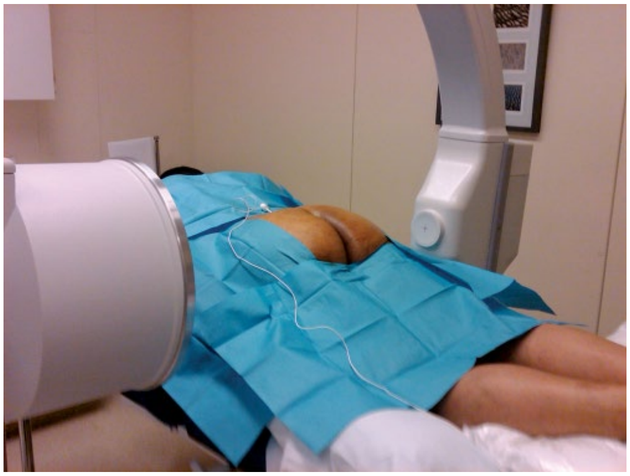

**Figure 166.1** Office-based percutaneous nerve evaluation (PNE) test. The patient is placed in the prone position with one or two pillows under the lower abdomen to improve the sacral approach with slight flexion at the hips. The patient's shoes and socks are removed to allow observation of the feet and toes. The sacrum, buttocks, and perineum are sterilely prepped with antiseptic solution and the sterile drapes are placed to allow visualization of the buttocks and gluteal crease area during the procedure.

The test period lasts for a few days up to one week. The patient maintains stimulation at a comfortable level and completes a 2–3 day voiding diary to provide objective data. The wire is then removed at 3–7 days by withdrawing the lead with gentle traction. A voiding diary is repeated a week later to make certain the patient returns to baseline voiding. The diaries are compared with the patient's pretest diary and, based on the patient's results, a final decision is made to proceed or not to proceed with permanent implantation. Usually, the patient needs to exhibit significant subjective improvement, and the voiding diary should show at least 50% improvement in voiding parameters (such as number of urge incontinence episodes) to warrant proceeding to implantation

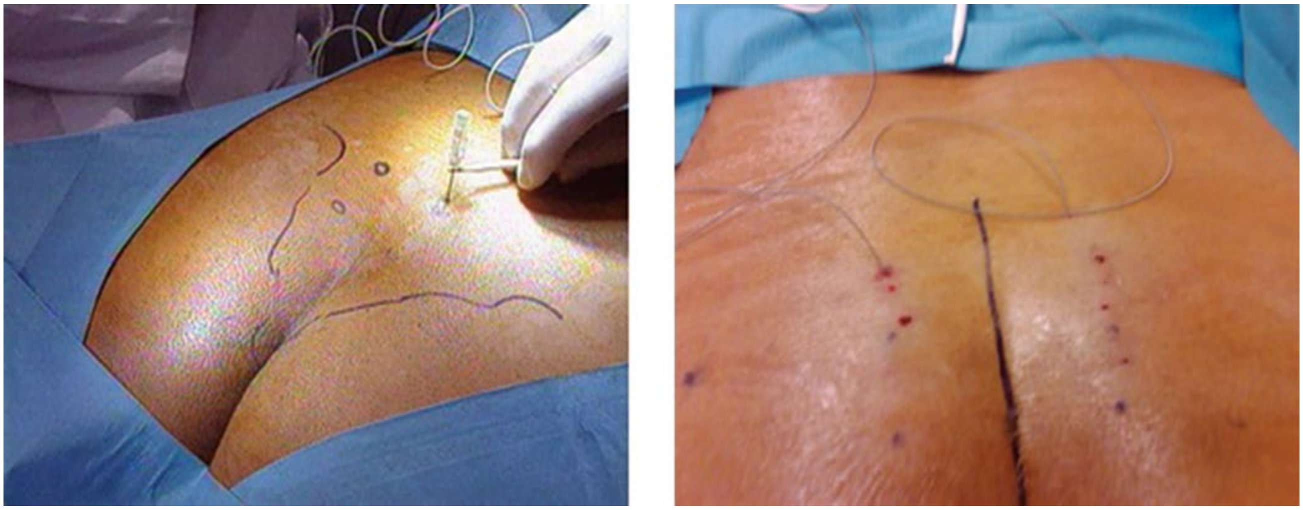

**Figure 166.2** Placement of the foramen needle. The sacral notches and coccygeal drop-off are identified by palpation or fluoroscopy. S3 is usually located 1.5–2 cm lateral to the midline at the level of the sacral notches, or about 9 cm above the coccygeal drop-off. Insulated foramen needles are inserted percutaneously into the foramen at a 60° angle relative to the skin in the S3 and S4 foramens under fluoroscopic guidance. The test stimulator is connected to the foramen needle via the test stimulation cable and stimulation is applied. The patient can try out left and right sides and decide on the best response. Bilateral test stimulation may be helpful for some patients who fail an initial trial with unilateral placement.

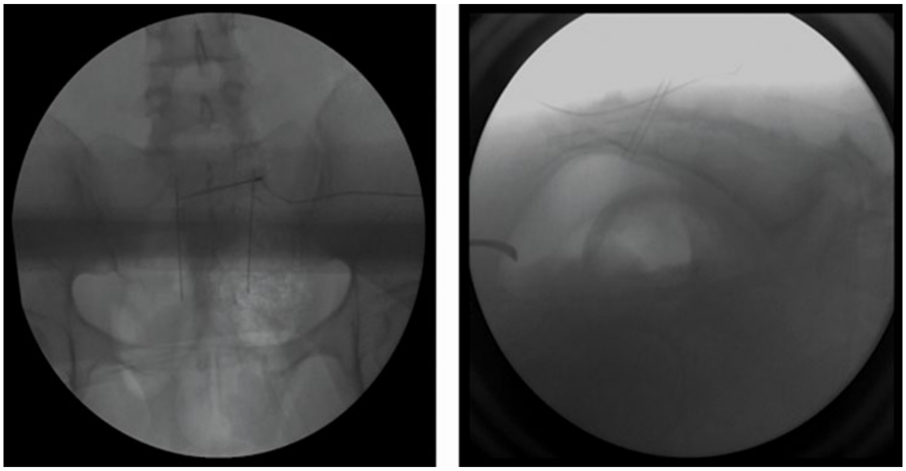

**Figure 166.3** Fluoroscopic images of foramen needles bilaterally at S3. Anterior–posterior and lateral views shown.

of the IPG. After an interval of two weeks or more, the patient is brought back to the operating room and a tined quadripolar lead electrode is placed with implantation of the IPG.

## Staged lead placement (first and second stage)

In equivocal cases, or if the insulated wires move or migrate, a trial can be carried out with a quadripolar tined electrode before making a final decision. In patients in whom sacral spinal anatomy may be distorted (i.e. congenital malformations, trauma, or surgery), or those who may not tolerate an office test stimulation, placement of a tined, quadripolar lead as a staged procedure under anesthesia (sedation or general) is recommended.

The initial procedure (first stage) is similar to the test stimulation described but is performed in the operating room under light sedation. During the surgery, prophylactic broad-spectrum antibiotics are provided and strict antiseptic precautions are maintained. While lying in the prone position, the patient is prepped with multiple layers of povidone-iodine, and again surgical drapes are positioned to allow for visualization of buttocks and gluteal crease area during the procedure as well as the patient's feet and ankles, which are left undraped to allow

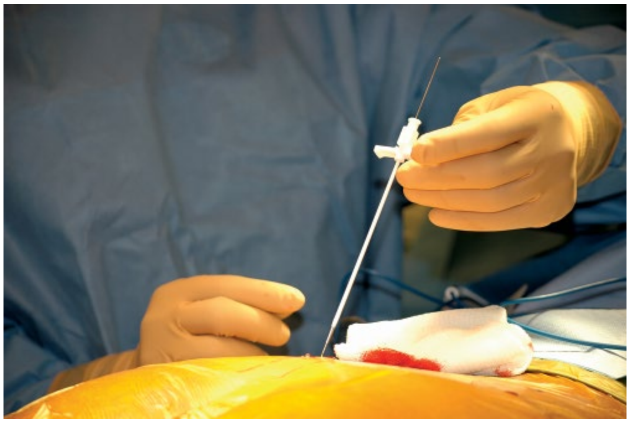

**Figure 166.4** Permanent lead placement. The lead introducer is inserted over the guidewire.

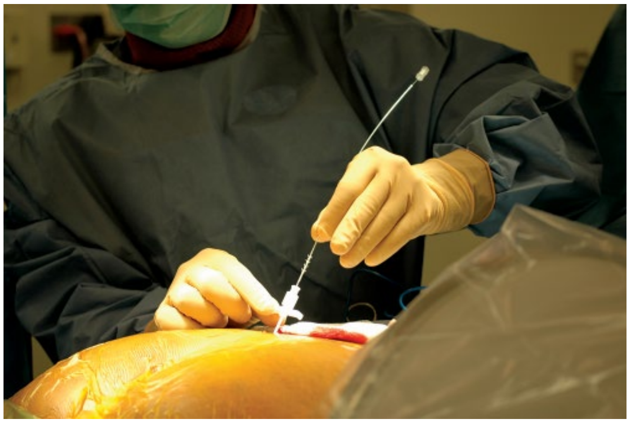

**Figure 166.5** Tined lead placement. The tined lead is inserted into the lead introducer sheath.

for observation for motor responses. In a similar fashion as described above for the PNE procedure, the S3 foramen is identified and an insulated foramen needle is placed in both foramens. Once the needles have been placed, with confirmation via fluoroscopy, and the sensory and motor responses obtained, a decision is made to use the best responses. The needle's stylet is removed, a guidewire is inserted, a scalpel is used to incise the skin along the wire, and the tract is dilated over the guidewire under fluoroscopic guidance using an introducer (Figure 166.4). Radiopaque markings on the introducer (one at the dilator tip and one at the introducer sheath tip) allow for appropriate positioning of the device within the S3 foramen. The sheath from the dilating apparatus is then left in; the tined lead (so called as it has tines that hold it in place) is inserted (Figure 166.5), and its position is optimized by again checking the neural responses. The sheath is then removed, and the tines are activated to hold the lead in place.

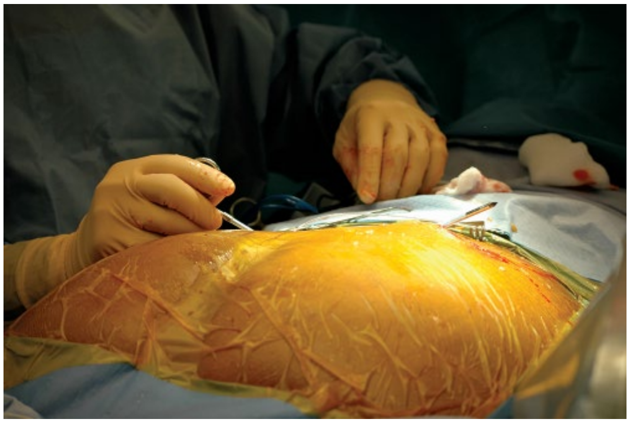

**Figure 166.6** With the bladed tunneling device the permanent lead is tunneled subcutaneously to the medial aspect of the lateral buttock incision (location of the eventual implantable pulse generator (IPG) site). Redundant lead wire and connection covers are buried in the subcutaneous pocket. Another tunnel is then created to externalize the connection further laterally to exit superolaterally to the IPG site to prevent infection.

A 3 cm skin incision is made in the contralateral upper buttocks, and a small subcutaneous pocket is created, which will be the future site of the IPG. The tined lead is now tunneled to the location of the eventual IPG, where it is connected to an externalizing wire, and then another tunnel is created to externalize the connection and to prevent infection (Figure 166.6). Redundant lead wire and connection covers are buried in the subcutaneous pocket previously developed, and the subcutaneous tissue and overlying skin are closed with absorbable sutures in two layers. If the patient reports more than 50% improvement in symptoms, a stage 2 procedure is performed, in which the external connection is removed and the IPG is placed (Figures 166.7 and 166.8). The IPG is programmed, and the patient is taught to set the unit at a comfortable setting at which the stimulation can be felt but is not painful. The patient is able to control the amplitude and to turn the unit on and off; the IPG is completely programmable using an external programmer. Thus, the various parameters can be adjusted on a routine basis as necessary to provide optimal stimulation and results.

Implantation of the IPG (stage 2) after a trial period with a quadripolar lead (stage 1) is sometimes referred to a two-stage procedure. When both the quadripolar permanent lead and IPG are implanted in the same operating room setting, generally after an office-based test stimulation, this is referred to as a complete or one-stage procedure.

Patients who have undergone successful test stimulation may be considered for implantation of the currently available neurostimulator, the InterStim® device (Medtronic, Inc., Minneapolis, MN, USA). The patient should understand fully the benefits and risks of the

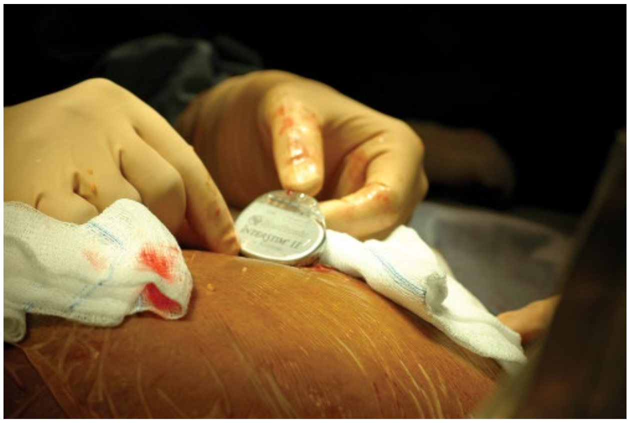

**Figure 166.7** Implantable pulse generator (IPG) implantation. During the second-stage procedure, the external connection is removed and the IPG is connected to the tined stimulation lead and placed in a subcutaneous pocket that is large enough to accommodate the IPG without any tension and with enough overlying tissue to prevent erosion. The overlying skin is closed with absorbable sutures.

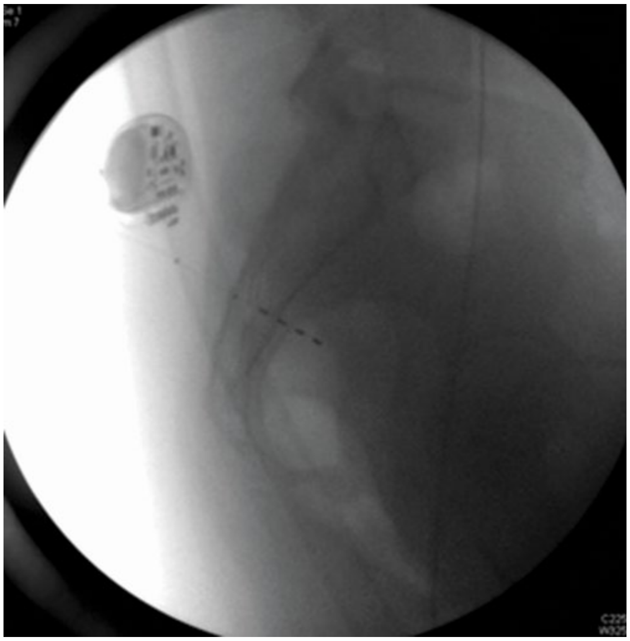

**Figure 166.8** Fluoroscopic image of tined lead placement, with implantable pulse generator contralateral upper buttock (lateral view). The lead is inserted until the first electrical contact point is straddling the ventral aspect of the S3 foramen.

procedure and that the battery life is limited to 2–5 years, depending on the settings. Patients who may become pregnant should consider alternative therapies, since the effect of neurostimulation on the fetus is unknown. Foreseeable need for MRI is also a relative contraindication to neurostimulator implantation (e.g. patients with multiple sclerosis).

**Table 166.1** Sacral nerve root motor and sensory responses to electrical stimulation.

| Nerve root | Pelvic floor | Lower extremity | Sensation |
|---|---|---|---|
| S2 | "Clamp" of anal sphincter | Leg/hip rotation, plantarflexion of entire foot, calf cramping | Sensations in base of penis/ vagina, and buttocks |
| S3 | "Bellows" response (levator muscles contraction) | Greater toe flexion | Pulling in rectum, extending forward to scrotum or labia |
| S4 | "Bellows" response | None | Pulling in rectum only |

## Sensory and motor neural responses

Intraoperative motor and sensory neural responses guide lead positioning during the test stimulation (Table 166.1). Sensory responses generally include a tingling, pulling, or vibratory sensation in the vagina and rectum in women and in the scrotum, phallus, and rectum in men. Motor responses include levator tightening (bellows response) and flexion of the big toe. Sometimes at S3, a plantarflexion of the entire foot is noted. In such cases, S4 may be the more appropriate foramen, as most patients are significantly bothered by such a foot response. An intraoperative motor response during the test procedure generally is considered to be more predictive of success after IPG implantation than a purely sensory response [34]. Although intraoperative motor responses are the primary neural responses used to locate the ideal site of electrode implantation, neuromodulation amplitude is usually applied at a level below that is needed to stimulate a motor response. The patient may use sensory perception to stimulation as an indicator of continued neuromodulation. Loss of sensory perception after implantation may herald a loss in benefit from neurostimulation.

## Permanent versus temporary lead test procedure

A major consideration for the clinician is whether to pursue an office-based test procedure, which, if successful, is followed by a "one-stage" implant of permanent lead and an IPG in the operating room. An alternative approach is the "two-stage" procedure, in which the patient has permanent quadripolar tined leads implanted in the operating room. The patient undergoes a trial period; if this is successful they then return to the operating room for tunneling of the leads and placement of an IPG.

Since the introduction of permanent quadripolar tined leads for test stimulation in 1997, multiple groups have published on the successful use of these leads. Today, most physicians in the United States perform a test procedure with these leads. One advantage of the quadripolar lead test procedure is that the same responses should be obtained once the external neurostimulator is replaced by the permanent IPG because the lead–nerve interface does not change. In theory, the tines should prevent lead migration and thereby allow a longer test period of up to two weeks.

A few studies have directly compared outcomes using temporary leads in the office compared with permanent tined lead placement in the operating room. In one recent nonrandomized study, Leong et al. [35] compared the patients' response rate to the PNE test and the first-stage tined lead placement test for SNS. They observed that in 69 patients with OAB when PNE was followed by stage 1 implantation, 47% had a positive response to PNE and 69% had a positive response to stage 1 implantation, which was statistically significant, suggesting that an additional 22% of patients may be salvaged with stage 1 implantation. A longer trial, up to two weeks, appears to increase eligibility for implantation, possibly because it takes some patients a longer time to adjust settings or otherwise achieve therapeutic benefit [36]. In practice, trial periods longer than two weeks are uncommon, primarily because of the potential for increased risk for infection. Furthermore, the manufacturer recommendation is not to exceed a two-week trial period.

Whether there is an advantage in performing a one-stage rather than a two-stage procedure has been evaluated. Everaert et al. [37] in a prospective trial randomized 41 patients who had a successful trial procedure with temporary leads to either direct IPG implantation (one-stage) or to undergo a test procedure with tined leads before implantation (two-stage). At 24 months of follow-up, patients who underwent a two-stage procedure had a lower rate of failure compared to the patients who had undergone a single-stage procedure (14% vs. 33%).

Overall, it seems that an office-based test procedure remains a reasonable option for most patients, and that a successful test procedure generally portends a good outcome after implantation. A test procedure with tined leads placed in the operating room may be more suitable for patients in whom the test procedure is equivocal, for patients who may require a longer test period to evaluate efficacy, and for patients in whom lead migration is suspected. Many experienced implanters, including the senior author, start with an office test stimulation in most patients.

## Percutaneous tibial nerve stimulation

The posterior tibial nerve is a mixed sensory–motor nerve, with axons from L4 to S3 spinal roots. It is thought that electrical stimuli of these nerve inhibits bladder activity, which then evokes a central inhibition of the micturition reflex pathway in the spinal cord and brain. McPherson first demonstrated in a cat model in 1966 that stimulation of cut ends of peripheral nerves, including the posterior tibial nerve, inhibited bladder contractions [38]. Almost two decades later in 1983, McGuire et al. applied electrical stimulation of hindquarter nerves to treat detrusor instability in spinal cord-injured nonhuman primates [39]. They later on went on to demonstrate its efficacy in humans with stimulation of the posterior tibial nerve [12]. PTNS was approved by the FDA in 2000 for OAB and has the advantage of lacking a permanent implant.

The current practice of PTNS treatment generally uses a 34-gauge needle electrode that is inserted approximately 5 cm cephalad to the medial malleolus and slightly posterior to the tibia. The needle is inserted at a 60° angle, and advanced to a depth of approximately 4 cm. A surface electrode is placed on the calcaneus of the ipsilateral foot. The electrode and needle are connected to a battery-powered stimulator, which is set at a current of 0.5–9.0 mA at 20 Hz, based on motor and sensory responses. Appropriate needle localization is verified by great toe plantarflexion or fanning of digits 2 through 5 in response to an initially higher amplitude stimulation. The patient generally undergoes treatment for 30 minutes weekly for 12 weeks. During this treatment period, patients complete voiding and pain diaries to ensure improvement of their symptoms. This is followed by treatments as needed based on patient symptoms. The procedure can be performed in the office without anesthesia and has minimal adverse effects. Currently, there is only one PTNS system commercially available, The Urgent® PC Neuromodulation System (Uroplasty Inc., Minnetonka, MN, USA).

### Percutaneous tibial nerve stimulation efficacy and outcomes

PTNS has shown good efficacy in the treatment of OAB symptoms with several studies demonstrating success rates of about 60–70% [40, 41]. In the Study of Urgent PC vs. Sham Effectiveness in Treatment of Overactive Bladder Symptoms (SUmiT) trial [41], 220 patients with OAB were randomized to receive either PTNS or a sham therapy. Compared with patients receiving sham therapy, patients who received PTNS had significant improvements in urinary frequency, urgency, urge incontinence episodes, and nocturia; 54.5% of patients receiving PTNS compared with 20.9% of patients receiving sham therapy reported moderate to marked improvements in global response assessment [41]. These findings were confirmed in a European study randomizing 35 women with medication refractory OAB to either PTNS or placebo (electrical stimulation of the gastrocnemius muscle). In that study, 71% of patients receiving PTNS reported improvement compared with 0% in the placebo group [40].

PTNS also has an effect equivalent or superior to anticholinergic medications but with a lower side-effects profile. In the Overactive Bladder Innovative Therapy trial, 100 patients were randomized to either 12 weeks of PTNS without pharmacotherapy or tolterodine extended release 4 mg. A global response assessment demonstrated significantly more patients reporting substantial improvement with PTNS compared with tolterodine (79.5% vs. 54.8%) [42]. However, both treatments led to similar objective improvements in terms of urinary frequency and urge incontinence episodes, leading the investigators to conclude that PTNS offered efficacy similar to that of tolterodine.

It is well known that both anticholinergics and sacral neuromodulation lose their efficacy when they are discontinued. However, an important advantage of PTNS is that it seems to provide a prolonged carryover effect with sustained symptom improvement even when the nerve is not being stimulated [43]. The Sustained Therapeutic Effects of Percutaneous Tibial Nerve Stimulation (STEP) study examined this carryover effect by enrolling patients who demonstrated clinical improvement after 12 weekly sessions. Study participants were prescribed a fixed-schedule 14-week tapering protocol followed by a personal treatment plan aimed at sustaining overactive bladder symptom improvement. Over a 36-month period, 77% of patients sustained moderate or marked improvement in all domains (nighttime voids, urge incontinence episodes, quality of life, $P < 0.0001$), requiring only an average of 1.1 treatments per month [44].

## Complications

Over the years, percutaneous test stimulations have been exceedingly safe, and complications at the preimplantation stage are rare. The main problem with temporary lead test procedures is lead migration reported at a rate of about 10–15%; however, this rate is lower when tined leads are used [19]. With placement of the IPG in the upper buttock region rather than the abdomen, significant decrease in IPG site pain has been recorded [19]. Infection rates have been reported to be between 5% and 10% [19, 45]. The overall revision rate reported in the literature is approximately 20–30% [19, 45–47].

According to published data in the literature, PTNS is safe and well tolerated. Complications of percutaneous tibial nerve stimulation are rarely reported. As with acupuncture, patients may experience a temporary discomfort during the initial needle placement as it travels through skin; however, there is minimal pain reported as the needle enters the deeper tissues. Nevertheless, future studies should continue to evaluate safety data of the technique.

## Cost considerations

Disadvantages of SNS include high initial treatment costs because of device costs, operating room and anesthesia costs for implantation. SNS must have excellent long-term efficacy to justify initial costs. Watanabe et al. estimated that the initial cost for SNS was US$22 226 but that is likely a significant underestimate [48]. An office-based test procedure is useful in identifying patients who are likely to fail implantation and since an office-based test procedure is significantly less expensive than an operating room procedure with permanent leads, it should help reduce cost. In the randomized trial by Everaert et al. [37], costs per patient were about €2000 higher for patients undergoing a two-stage procedure. The added benefit of a longer test period and of not implanting an IPG in patients who fail a test procedure with permanent leads may offset this cost difference somewhat. Cost-effectiveness modeling studies have been limited and generally compared neuromodulation to other entities such as botulinum toxin injection [49].

A major limitation of PTNS as a treatment option is the financial burden/time requirement for some patients and families who need to travel to the office weekly for stimulation. There is currently a significant amount of ongoing research examining home administration systems and micro implants which may improve patient access and treatment compliance while improving treatment costs. Although overall success rates may seem similar for PTNS and SNS, comparisons are quite difficult because the populations undergoing each of these treatment options is quite different. A recent cost-effectiveness study used estimated success rates as 67% for PTNS versus 55.4% for an SNS test stimulation. A slightly higher percentage (90% vs. 71%) remained on therapy with SNS versus PTNS after a successful initial treatment, but at a significantly higher cost (US$24 342 vs. US$4867) [50]. It is clear that appropriately randomized long-term studies are needed to better understand the cost-effectiveness of neuromodulation.

## Summary

Common voiding disorders including OAB, nonobstructive urinary retention, and pelvic pain affect millions of patients' quality of life with associated high economic costs. For patients with OAB, many treatment options are available. First-line treatment options remain pelvic floor rehabilitation and behavioral therapies and second-line options would be anticholinergic and other medications. Although antimuscarinic drugs can reduce voiding symptoms, many patients do not tolerate the side-effects, and some do not experience sufficient relief. More invasive treatment modalities such as surgery are indicated in patients who are refractory to medical management and have persistent urinary morbidity. Modulation of bladder reflex pathways with office-based procedures, such as SNS and PTNS, have proven to be efficacious. Since their approval for OAB symptoms, these treatment modalities have grown in popularity, with multiple case series and randomized controlled trials demonstrating adequate safety and efficacy. PTNS has the benefit of being an office-based procedure with relatively low cost, while SNS has the advantage of permanent implantation with constant electrical stimulation, avoiding the need for weekly or monthly office visits.

Given the relatively high cost of the SNS procedure, patient selection remains a challenge for the clinician. Factors predicting a response to SNS for OAB symptoms are not well known. Physicians must depend on their clinical acumen and a test procedure to identify appropriate candidates for IPG implantation. Whether office-based percutaneous test stimulation is initially carried out or whether the tined quadripolar lead is initially placed remains at the discretion/experience of the clinician and patient preference. The office-based procedure is inexpensive and provides the patient and physician with valuable information to make an informed decision about proceeding further. The advantages of the permanent lead include decreased lead migration and a longer test period of up to two weeks. Furthermore, with the permanent lead, the patient will have the exact same sensory and motor responses during the test phase as the permanent implant as the lead remains unchanged. However, permanent leads require placement under monitored anesthesia care, have an increased cost, and will require two procedures in the operating room even if unsuccessful. With the continued evolution of the procedure, complication and revision rates are gradually decreasing.

As ongoing research provides insight into the mechanism of action of neuromodulation, expanding indications for its usage are likely to be found. Efforts now turn to developing even smaller devices with rechargeable batteries with the goals of making the procedure less invasive. Hopefully, these improvements will not come at increased cost to an already expensive healthcare system. Therefore, further innovation to provide better access to care and improved cost-effectiveness is needed for SNS and PTNS to endure as a treatment option for voiding disorders.
